PREFACE

Twenty years ago it was freely predicted by a number of eminent workers that a new era of bacteriology was beginning which would be characterized by a greater emphasis upon the nature of these microorganisms, and especially their biochemical physiology. This has been more than amply confirmed in recent years, and it is becoming increasingly clear that bacteriology has largely emerged from a naturalist period of essentially empirical observation into an analytical, quantitative phase in which the proof of specific bacterial etiology of infectious disease, for example, has been extended into analysis of the functional mechanisms of pathogenesis. The changing approach has given great promise, and the extent to which a book of this kind becomes appreciably obsolete within a few short years is impressive evidence of the progress that has resulted from it. Most encouraging is the extent to which the various applied branches of bacteriology are drawing together on a common fundamental basis, and the relating of these forms to other organisms through basic physiological processes, such as respiration, nutrition and genetic control.

The pattern is reflected in the development of this book through successive editions, its basic premise has been the assumption that the sound pedagogical approach is that of an understanding of fundamental principles out of which application flows. There are few better illustrations of the importance of apparently impractical "pure" research than the elucidation of the nutritional requirements of bacteria, with subsequent development of a rational theory of chemotherapy. This area of research further points up the significance of the anabolic phase of bacterial metabolism as accumulating evidence suggests more and more strongly that the point of attack of certain of the antibacterial drugs is in the reactions of synthesis. In this same vein, the apparently academic question of the relative importance of, on the one hand, selection of chance mutants, and, on the other, a mass action basis of adaptive enzyme formation in the development of drug-fast strains of pathogenic bacteria may, perhaps, prove to be of considerable significance through mutually exclusive adaptations. Considerations such as these tend to reinforce belief in the validity of the premise, and it continues as the basis of the present edition.

There has been, necessarily, a considerable amount of rewriting which has ranged in extent from entire chapters to sections, together with appropriate modification of innumerable minor points. One change in order of presentation has been made with a shift of the chapter on bacterial physiology so that it precedes that on physical and chemical agents.

The chapter on laboratory methods has been completely rewritten in a much more specific form. It is in no way intended to be exhaustive, but rather to include only the majority of the common laboratory procedures which the student will use, and to make available to him specific information concerning

CHAPTER	PA

INDEX TO VOLUMES I AND II	i-xlvi

them. Many of these are, of course, amplified and extended in subsequent sections on the bacteriological diagnosis of the various infectious diseases. In the preparation of this material the writer has drawn heavily on the *Manual of Methods of the Society of American Bacteriologists* and on *Diagnostic Procedures and Reagents* of the American Public Health Association in an effort toward further standardization of laboratory procedure at this basic level. The chapter on streptococci has also been completely rewritten with closer integration of these bacteria as a group of pathogens, and a relating of the various clinical forms of infection on this common basis. The rapid advances of the past few years in bacterial genetics have necessitated a reconsideration of bacterial variation, and this chapter has likewise been entirely rewritten in a somewhat different form with consideration of the observed variations, the relation of these to one another, and finally the questions of underlying mechanisms. In conjunction with this, the earlier section on the effects of radiation has also been rewritten.

A considerable number of sections have also been rewritten. These include the sections on respiration and carbohydrate metabolism, in which greater emphasis has been placed on the cyclic nature of these processes together with integration of the modes of formation of the products of carbohydrate metabolism as a generalization of pyruvate metabolism. Sections on the biosynthesis of carbohydrate and amino acids have also been added, and the catalysis of these and the catabolic phases of metabolism related to nutritive requirements. Similarly, the discussion of the mechanisms of antibacterial action has been rewritten and extended, and related more closely to bacterial physiology. The section on hypersensitivity has been revised also, with correlation of clinical disease with basic immunological phenomena, and entirely new sections on *Donovania*, rickettsialpox and infectious hepatitis have been added.

Other more general changes include the addition of a considerable number of electron micrographs, and more recent data on the seasonal incidence of infectious disease. As to the former, only relatively recently has resolution been such that electron microscopy has contributed to and become a valuable adjunct in the study of bacterial morphology. Its value is apparent in the demonstration of intracellular structures perhaps identical with nucleus-like chromatinic bodies, the convincing evidence of the origin and insertion of flagella, the elucidation of the details of L type reproduction, and other hitherto obscure problems. Electron micrographs have, therefore, been freely used to illustrate these and other matters, but have not been substituted for photomicrographs which remain, of course, invaluable to the student.

The writer is greatly indebted to his collaborators, Dr. F. B. Gordon who is responsible for the viruses, Dr. R. J. Porter who has continued his responsibility for medical parasitology, and Dr. J. W. Moulder who, with this edition, has taken over the general subject of bacterial physiology and has written the sections on respiration, carbohydrate metabolism and synthesis. These contributions are now recognized on the new title page coincident with the dropping of the name of Dr. E. O. Jordan as co-author. With the rewriting of this book through successive editions since Dr. Jordan's death thirteen years ago, his connection with it has become so tenuous that his name can no longer

The phenomena that present themselves for study are derived from the most diverse sources. Some come to us from epidemiology, using that term in its widest sense. Under natural conditions different animal species show a widely differing incidence of certain infections. Thus, anthrax is in the main a disease of herbivora. Of the animals dying of anthrax in this country in 1914, 733 were cattle, 5 were sheep, 32 were swine and 25 were horses. In Australia and South America sheep are more commonly affected; but Algerian sheep are stated to be highly resistant. Tuberculosis is one of the commonest natural infections of man and cattle. It is common in pigs and in fowls. It is relatively uncommon in sheep, goats, horses, cats and dogs; and very uncommon as a natural disease in rabbits, guinea-pigs, hamsters, rats and mice. Among mankind there are well-marked racial differences in its incidence and severity. In eight of the great cities of the United States in 1920 the mortality from tuberculosis among the white population varied from 0.794 to 1.216 per 1,000 living; among the coloured population it varied from 2.855 to 4.205 per 1,000. Such instances could be multiplied *ad nauseam*.

The epidemiologist also records differences in the incidence and fatality of various infective diseases at different ages, suggesting in many cases an increase in resistance with age. He notes also that repeated attacks of the same infective diseases are in some instances very rare, as in measles, or smallpox, or diphtheria, or typhoid fever, whereas in others they are relatively common, as in influenza, or pneumonia, or the common cold.

Other data come to us from clinical medicine in the narrower sense. Infections that, in their usual course, progress slowly to death or recovery sometimes assume a fulminating form. Such a protean infection as tuberculosis shows the greatest diversity in the varying prominence of its local and general manifestations. In any infective disease we are confronted with a wide variety of circumstances in which some patients die and some recover.

For the immunologist these are crude facts that require analysis. Using his own methods he re-examines the phenomena presented by natural infection. Sometimes he transforms the picture they present. He finds, for instance, that the recorded frequency of natural tuberculosis in various animal species does not in all cases reflect their relative resistance to experimental infection (see Chapter 59). He discovers also that there may be a diversity of immunological states within a single clinical syndrome. This is true of tuberculosis; there are different types of the tubercle bacillus, and a given host species is more resistant to one type than to another. It is true of lobar pneumonia. For the immunologist this is not one disease but several, each caused by a significantly different type of pneumococcus; and he notes that the statement that second attacks of pneumonia are not uncommon may belong to the Baconian category of a truth that has in it a mixture of a lie. Again he finds that enteric fever is not one but many; and his attempts at interference are planned accordingly.

Another important change that the immunologist makes in the clinical and epidemiological picture is in regard to the character and extent of the association between any given parasite and the host species that it infects. He finds that the real range of interaction includes states of equilibrium in which the host shows no overt signs of disease. Whether we call all these conditions latent infections, or refer to many of the hosts as healthy carriers, matters little. No hair-splitting definition will help us much. The significant thing we have learned is that in some infections, such as measles, contact between a previously uninfected host

be asked to carry the burden of responsibility for authorship, but is retained in the title as a token of the writer's deep affection and respect.

The number of colleagues who have taken the time and trouble to offer suggestions and criticisms is very great indeed. The writer's obligation to them all can hardly be overestimated, and he hopes that they will continue to offer such invaluable advice. Of these, the writer is especially indebted to Dr. Stuart Mudd and his co-workers for advice and assistance regarding electron micrographs and newer studies of bacterial morphology, to Dr. C. Robinow for photomicrographs of his chromatinic bodies, to Dr. Robinow and Miss Woudera van Iterson for electron micrographs of flagella, to Dr. R. W. G. Wyckoff for his superb micrographs showing phage generation, and to Dr. W. A. Jamieson who allowed the writer free access to the entire collection of electron micrographs of the Lilly Research Laboratories. Last, and by no means least, the writer is deeply appreciative of the help of Mrs. Gertrude Conklin and that of the staff of the W. B. Saunders Company in carrying this book through the press to its final form.

August, 1949

WILLIAM BURROWS

the existence of an indeterminate borderline class, he is justified in using the classification, because most of the time the distinction can be usefully made.

And so, if he has a taste for classification, the immunologist can draw up some such list as this:

1. Innate Immunity (i) Non-specific.
 (ii) Specific.
2. Acquired Immunity (i) Non-specific.
 (ii) Specific.
 - (a) Active.
 - (α) Naturally acquired.
 - (β) Artificially induced.
 - (b) Passive.
 - (α) Naturally acquired (congenital).
 - (β) Artificially induced.

Innate, or Genetic, Immunity.

Of innate as opposed to acquired immunity, we have noted that different animal species may display wide differences in their resistance to various bacterial parasites, or to their toxins. This species immunity is of great practical importance in relation to the communicability of infective disease from animals to man, or from one animal species to another.

There can be no doubt that differences in innate resistance also occur within any animal species, one individual differing from another in this biological character as in any other. Of the extent of these differences and of the laws that govern their inheritance we as yet know very little. It is obviously difficult to obtain unequivocal evidence in man for the inheritance of susceptibility to a given infection from field studies of human populations. Nevertheless, the evidence is highly suggestive in some infections, for example, in leprosy (Aycock 1941), poliomyelitis (Aycock 1942), tuberculosis (Chapter 58), and rheumatic fever (Chapter 68). A number of workers have studied this problem by direct experiment, and their results indicate that it is possible to increase or lower the average resistance of a given strain of rats, mice or other experimental animals, by selective breeding. (See for instance Rich 1923, Webster 1923, 1924*a, b*, 1925, 1933*a, b*, Pritchett 1925, 1926*a, b*, Lambert and Knox 1928, Irwin 1929, 1933, Irwin and Hughes 1931, 1933, Lambert 1932, Schott 1932, Gowen 1933, Gowen and Schott 1933*a, b, c*, Schütze *et al.* 1936, Hill *et al.*, 1940, Lurie 1941, Gowen and Calhoun 1943.)

Experiments of this type are, however, subject to great technical difficulties. The obvious method of obtaining a strain of animals with a high genetic resistance is to infect an adequate sample with the bacterium under study, breed from the survivors, and repeat the process through several subsequent generations. This plan has, in fact, been followed by some of the workers referred to above; but it is clearly open to serious sources of error. In testing the resistance of our original generation we shall certainly alter it, and the effect of this alteration will not be confined to the parent animals. The surviving females will pass on a temporary passive immunity to their young; and, since most of the species commonly employed in such tests attain sexual maturity within a few months at most, this congenital passive immunity may persist until the F_1 generation are tested. A much

We are still largely ignorant of the defence mechanisms whose effectiveness is determined genetically. Gorer and Schütze (1938) found some evidence that in a strain of mice resistant to *Salm. typhi-murium* the specific antibody response to the H antigen was better than in a susceptible strain, but this relation did not hold for O antigen, nor for the H or O antigens of *Salm. enteritidis*. Lurie (1941), on the other hand, working with inbred strains of rabbits, of low and high resistance, demonstrated that both the degree of cellular response to invasion by the bovine tubercle bacillus, and of skin response to the injection of heat-killed bacilli, was higher in the tuberculosis-resistant strains (see p. 1490). A similar, and more obvious rapid development of the cellular reactions, and to some extent of antibody response, was observed when the same strains of rabbit were tested by inhalation of a less rabbit-virulent human strain of tubercle bacillus (Lurie *et al.*, 1952). In inbred strains of mice selected for resistance to *Salm. typhi-murium* the degree of resistance was found by Gowen and Calhoun (1943) to be correlated with the mean number of leucocytes circulating in the blood. A large number of circulating leucocytes, however, is probably a manifestation of a general not of a specific resistance to the organism, for as Reich and Dunning (1941) showed in rats, the numbers of leucocytes may be correlated with general fitness for survival.

Severens, Roberts and Card (1944) studied the defence mechanism in two breeds of hen, which as chicks aged 1-10 days were respectively susceptible and resistant to infection with *Salm. pullorum*. All the demonstrable differences in the reactions of the two breeds were connected with lymphocytes. Age for age, the number of circulating lymphocytes, the rate of their normal increase after hatching, and the number present in the tissues of the spleen, were all greater in the resistant breed of chick. Moreover, splenectomy reduced both resistance and the circulating lymphocytes in the resistant chicks, but had little effect on the susceptible. It is suggested that the greater availability of lymphocytes may have increased the resistance by providing large numbers of precursors for macrophages in the tissues of the resistant chicks.

There may also be genetic differences in the ability of phagocytes to digest the pathogen. The splenic reticulo-endothelial cells of mice resistant to *Salm. typhi-murium* digest the invader rapidly, and those of susceptible mice digest it very little; moreover, whereas the salmonella inflicts metabolic damage on the whole liver in the susceptible strain, in the resistant it produces a few severe lesions in an otherwise healthy liver (Oakberg 1946). In selected strains of fowls tested with *Salm. gallinarum*, Bell (1949) recorded an association of resistance with the ability of the circulating polymorphonuclear leucocytes to digest the salmonella *in vitro*. He also noted a slightly higher body temperature, and greater capacity to maintain the body temperature when subject to low air temperatures, in the more resistant strains. Weir (1949) recorded in mice an association of higher mean blood pH with resistance to *Salm. typhi-murium* (of the order of 7.4, as against 7.33 in susceptible) both in mouse strains as a whole, and in the individuals of populations resulting from crosses between resistants and susceptibles. But when strains were bred for high and low leucocyte counts, and high and low pH respectively, it was found that mice with low leucocyte counts and low pH were the most resistant (Weir *et al.* 1953). If it is assumed that blood leucocytes and pH do in fact contribute to defence against infection, then resistance depends on complex interactions of characters which, taken independently, do not necessarily contribute to resistance. Again, if we assume that intoxication by bacillary

and repeated the procedure for ten generations. The strain was resistant to the toxin as compared with control unselected mice, but in spite of this it had not acquired any resistance to infection with the living bacillus.

In summary, then, we have undoubted examples of heritable resistance to certain experimental infections; resistance which by breeding can be selected without exposure to the infection in question, and which in some cases has proved, in comparisons of

less frequent, local lesions common and relatively extensive, and latent infections increasing in frequency.

With partial immunity of a high grade, death no longer occurs, bacteraemia is infrequent and, when it occurs, is slight and transient. Local lesions are becoming much less frequent and, when they occur, much less extensive. Latent infections reach a maximum frequency and then begin to decline.

FIG. 239.

Finally we reach the limit—perhaps never fully attained—of complete or solid immunity. The host is entirely impervious to all attacks of the parasite.

It will not have escaped attention that the grades of resistance that we have labelled as partial immunity are compatible with severe and often fatal infections, and that many infective diseases in their common clinical form might be regarded as occurring in partially immune persons. This view is almost certainly the right one. The syndromes that normally characterize such diseases as typhoid fever,

will learn something from their success or their failure. In medicine this is not always the case, simply because the practice of medicine is a much more difficult thing than any kind of mechanical industry, or indeed than any industrial process at all.

It may be quite easy to tell when an immunological procedure is an unqualified practical success. It is much more difficult to tell whether it is a partial success, or an unqualified failure. And this cause of confusion, which in truth affects the immunologist in the laboratory almost as much as the physician in the ward, is so important that it deserves a separate chapter.

will learn something from their success or their failure. In medicine this is not always the case, simply because the practice of medicine is a much more difficult thing than any kind of mechanical industry, or indeed than any industrial process at all.

It may be quite easy to tell when an immunological procedure is an unqualified practical success. It is much more difficult to tell whether it is a partial success, or an unqualified failure. And this cause of confusion, which in truth affects the immunologist in the laboratory almost as much as the physician in the ward, is so important that it deserves a separate chapter.

here to a brief discussion of some general principles, with illustrative examples drawn from a few immunological problems.

The cause of our troubles is sufficiently obvious. It was set out very clearly by Greenwood (1921) and by Yule (1921). The worker in the more exact sciences can reduce his uncontrollable variables to a small and often to a negligible residuum, and can so obtain constantly reproducible results. We cannot. In experiments, on living animals, and still more in assessing the value of therapeutic or prophylactic procedures in man, we cannot exclude the interplay of factors about which we know little, except that they are certainly very numerous and may be very important. We cannot avoid an element of randomness in our observations; but, if we have planned our experiments wisely and fortune has been kind in eliminating major disturbing factors that we could not have foreseen, this randomness will be of the sort which we can express in numerical values and whose effects can therefore be assessed with some accuracy in the interpretation of our results.

It will simplify discussion to consider in turn a series of problems of the kind that are continually presenting themselves for solution.

THE MEASUREMENT OF RESISTANCE

To take the most obvious problem, though not the simplest, how can we measure the resistance of an animal to a particular parasite or to its toxin? Suppose first that we wish to measure directly the resistance of the animal as a whole, taking death or survival as our test. Then it is only under quite exceptional conditions that we can obtain *any* measurement on a single animal. If we are dealing with a very powerful toxin that kills rapidly, within a few minutes or hours, it is sometimes possible to give repeated and increasing doses at short intervals and so to measure approximately the amount which is necessary to cause death. But if our toxin acts more slowly, or if we are dealing with a living bacterium, this method cannot be employed. If we start with a small dose and the animal fails to die during the period—usually measured in days—within which we should expect death to occur, we cannot test it again by giving a larger dose, because our first dose will almost certainly have changed its resistance. It is not, from our present point of view, the same animal as before. If we start with a large dose and the animal dies, we do not know how it would have reacted to a smaller dose; if it lives, we know that it is resistant at that particular dose level, but we do not know and can never discover how it would have reacted to doses larger still. It is clear that, if we take death or survival as our test, we must deal with groups not with individuals. This condition is, in truth, usually implicit in the question we want to ask. We are not often interested in the resistance of a particular mouse, or guinea-pig, or rabbit, as such. We are almost always regarding the individual as a representative of a class—normal, or treated in some way that may, we think, have altered resistance to a particular bacterium or toxin—and few of us are naïve enough to believe in a standard guinea-pig, even if we confine ourselves to animals of a given breed, sex, age and weight. What we sometimes fail to realize is that we must, in most cases, test large numbers of animals before we can regard our result as representing truly the average behaviour of the class from which those animals are drawn.

There is another problem, intimately and necessarily bound up with that of measuring resistance, namely, the problem of measuring, or at least specifying,

to our treated animals a large dose of bacteria or toxin, which experience has shown to be certainly fatal to all untreated animals of the same species, age, weight, etc., and note that the treated animals survive. But we shall be wise to make very sure about our "certainly fatal" dose, especially if our group of treated animals is small. We shall, indeed, always test a few untreated controls to guard against any gross experimental error.

But the increase in resistance may not be of this dramatic kind. Our treated animals may be unable to withstand a dose of bacteria or toxin that will kill all untreated controls, though the mortality in treated and untreated groups may differ appreciably. Our problem is to determine whether this observed difference is likely to have occurred as the result of chance.

In the following section, we discuss relatively simple examples and assume that the experimental animals behave according to expectations based on certain statistical arguments. Reference to modern text-books of statistics will show that we might have used other statistical concepts—and indeed, for more complex examples we should have had to do so. But our examples are sufficient to illustrate the mode of statistical argument, and to introduce the reader to some of the elementary terminology.

Suppose that we know, from an extended experience, that a particular experimental procedure causes an average death-rate p in a large group of animals. This rate, p , expressed as a fraction of unity (e.g. $p = 0.5$ for a 50 per cent., and 0.3 for a 30 per cent. death-rate), can also be taken as the probability of one animal dying. The probability of its living is $(1 - p) = q$; and q clearly is the survival rate among the animals, i.e. if the percentage mortality is 30, the percentage survival must be 70.

Supposing we know the true average mortality to be 0.5, how often are we likely, in a single test, to observe it? Two animals A and B are injected. The probability of A's dying is p and of B's dying is p , and of both dying is p^2 . The probability of both living is q^2 . The other possible results are (i) A's dying and B's living and (ii) B's living and A's dying; and in both cases the probability of the event is $p \times q$. The probability of one animal dying and the other living, irrespective of which does which, is $2pq$. We have therefore:

Probability of two deaths	p^2
Probability of one death	$2pq$
Probability of no death	q^2

These are the successive terms of the expansion of the expression $(p + q)^n$, where $n = 2$, and we obtain the results for larger groups of n animals by substituting the appropriate value for n in the expression. For instance, with four animals, the probability of getting 4, 3, 2, 1 or 0 deaths in any single test would be p^4 , $4p^3q$, $6p^2q^2$, $4pq^3$ and p^4 respectively. Both p and q are 0.5, so that these five terms are respectively 0.0625, 0.25, 0.375, 0.25, 0.0625, and represent the relative frequencies of each of the 5 possible events. They are plotted in Fig. 240A. The curves for B and C take us two steps further, being the relative frequencies when $n = 8$ and $n = 12$. As n increases, the figure becomes less step-like, and shows a decreasing proportion of its total area at each end of the base line. These figures represent distributions of the relative frequencies of the various possible events. The first important fact about a frequency distribution is the average, or mean, frequency, which is used to characterize the distribution. In A, B and C the mean frequency is in each case $n \times 0.5$, i.e. 2, 4 and 6 deaths respectively. The other frequencies are symmetrically disposed on either side of the mean. (The symmetrical disposition is the result of taking $p = q$. If we take $p = 0.3$, and therefore $q = 0.7$, the relative frequencies of 4, 3, 2, 1 and 0 deaths in a batch of 4 mice are given by the binomial expansion of $(0.3 + 0.7)^4$

that the 3 groups in A, B and C are not completely alike, even though all the animals are, by hypothesis, equally susceptible to the lethal agent. In A, for example, the frequency with which a deviation of ± 50 per cent. from the mean will occur by chance is p^4 , which is 0.0625 or about 6 times in 100 trials; whereas in C, the same deviation will occur by chance about twice in 10,000 trials, since p^{12} is 0.000244. More generally, as the relative heights of the columns in A and C show, the bigger deviations from the mean are less likely to occur in the test with the larger number of animals; and there is a greater probability of obtaining results near the expected mean death rate of 50 per cent. In comparing distributions, then, we must consider not only the mean, but also the range over which the deviations from the mean are spread; to do this we need a measure of the spread of deviations applicable to all distributions of this type. This measure we find in a value known as the standard deviation, which is the second important characteristic of a distribution.

For the better appreciation of the standard deviation, we shall consider a distribution that is more general in form than A, B or C. These are step-like collections of parallelograms, the area of each of which corresponds to the relative frequency of each event. If we make n very large, say 1,000, and reduce the scale upon which we record the events, the figure for $(p + q)^{1000}$ approximates to a continuous curve of the form D. This curve is known as the *normal curve*. The distribution of frequencies of a number of biological

TABLE 59

Deviation in Terms of the Standard Error; or Ratio between a Difference and its Standard Deviation.	Odds against this Deviation or Difference being the Result of Random Chance.

measurements, such as the height of human beings of a certain age, or the resistance of a certain type of animal to doses of a certain poison, approximates to this mathematically defined curve. In many of the measurements we make in the study of immunity, the deviations from mean values can be fitted to a normal curve, though not necessarily in the form of our raw data. The abscissae in Fig. 240, it happens, are on a linear scale. Normal distributions of this kind are not commonly found in nature; but, by suitable transformation of the variate that we measure into a logarithmic or other scale, we obtain a sufficient approximation to the normal curve for valid statistical calculations (see Gaddum 1945). For reasons that will be found in the statistical text-books, we may assume with some confidence that in the measurements of resistance, etc., with which we are mainly concerned in immunity, the deviations from a mean value will be distributed much as they are in the normal curve, and that the arithmetic of the normal curve will be applicable to most of our data.

The standard deviation of a distribution that approximates to the normal may be obtained arithmetically, by squaring all the deviations from the mean, adding the squares together, dividing the result by the total number of observations, and taking the square root. The resulting figure, the "root mean square deviation," is usually written as σ . It has a positive and a negative value and is correspondingly measured to the right and left of the mean in graphic representation of the distribution. In Fig. 240 D, for example, the base line has been marked off at $\pm \sigma$, $\pm 2\sigma$ and $\pm 3\sigma$, and verticals have been erected

(0.5 + 0.5)", the curve with which we are actually concerned will usually be asymmetrical, corresponding, for example, to the expansion of (0.3 + 0.7)", for we shall not necessarily be dealing with a test that gives an average mortality of 50 per cent. But if the number of animals in the group under test is not too small, say not less than twenty, and the chance of the less likely event, life or death whichever it may be, is not less than 0.2, the odds calculated on the basis of the standard deviation are sufficiently accurate.

It will, however, have been noted that we have, throughout the preceding discussion, assumed the possession of one very important piece of knowledge—the true average mortality of the procedure under test. Usually we do not know this and have to assume that it is in fact the mortality we observe in the course of our experiments. When we compare two groups of animals, one treated, the other not, we may get a difference in mortality. This difference may have arisen by chance; i.e. the treatment has had no influence on the result. In this case the most probable event is a difference of 0. But the results from each group may by chance vary round the mean, and if one result happens to deviate largely in the positive direction and the other in the negative, the chance difference may be large. If we repeated the comparison many times, we should expect the larger chance differences to be infrequent, the smaller ones more frequent, and differences of 0 to be most frequent. Now it is found that *differences* between pairs of mean values derived from two normal distributions are themselves distributed normally; and this distribution of *differences* has a standard deviation, or as it is usually called, a standard error. This standard error is easily obtained, since it is the square root of the sum of the squares of the standard errors of the two means from which the difference was derived. In our simple binomial examples, where x_1 and x_2 are the numbers of animals dying in the two groups, the standard error of a mean proportional death-rate x_1/n_1 found in a group of n_1 animals in which the expectation of death is p_1 is $\sqrt{p_1 q_1/n_1}$, and similarly of x_2/n_2 is $\sqrt{p_2 q_2/n_2}$. The standard error of the difference $x_2/n_2 - x_1/n_1 = d$, is then

$$\sqrt{p_1 q_1/n_1 + p_2 q_2/n_2}.$$

If the difference has arisen by chance, i.e., if the two groups do not differ in any significant way, the best measure we have of the real chance of death is the death rate in the 2 groups as a whole. This, the mean chance of death, is $(x_1 + x_2)/(n_1 + n_2)$, which we may call p_0 . The mean chance of survival, $q_0 = (1 - p_0)$. The standard error, then, of the mean x_1/n_1 is now $\sqrt{p_0 q_0/n_1}$ and that of x_2/n_2 is $\sqrt{p_0 q_0/n_2}$; and the standard error of the difference is $\sqrt{p_0 q_0 \left(\frac{1}{n_1} + \frac{1}{n_2} \right)}$ or if we are dealing in percentages

$$100 \sqrt{p_0 q_0 \left(\frac{1}{n_1} + \frac{1}{n_2} \right)}$$

Let us now take a concrete example. Thirty mice that had been repeatedly inoculated with a killed suspension of *Salm. typhi-murium* and 30 uninoculated mice to serve as controls were injected intraperitoneally with a constant dose (1,000 bacilli) of living *Salm. typhi-murium*. They were then observed over a period of 28 days. During this time 16 of the 30 vaccinated mice died of the infection, and 29 of the 30 controls. We may tabulate these results as follows:

Vaccinated.	14 = 46.67 per cent.
Controls	1 = 3.33 " "
Difference	13 = 43.34 " "

What are the odds against each of these observed differences in behaviour having been due to chance?

The experimental material can be tested for heterogeneity in various ways, though it is not often done. Lockhart (1926) divided a population of mice into groups of 20, gave each the same dose of a preparation of living *Salm. typhi-murium*, and observed them for 14 days. In one experiment with 9 groups, the deaths were 16, 16, 17, 19, 18, 17, 15, 17 and 14. This gives 36 differences between pairs. The largest observed difference, 19-14, should (Table 60) occur by chance only once in 27 comparisons. In a second experiment with 5 groups, the deaths were 18, 17, 13, 16 and 13. The largest difference, 18-13, occurs twice in 10 comparisons between pairs, and from Table 60, should occur by chance once in 17 comparisons. As far as they go, then, these figures and others we have not cited indicate within the limits of experimental error that Lockhart was reasonably successful in randomizing his experimental conditions. But had the distribution of deaths differed widely from that expected from the errors of random sampling, it would have been clear that disturbing factors had not been eliminated.

It is doubtful whether equally satisfactory results can always be attained in immunological tests of this kind. The possible disturbing factors are legion; so that unless there is good technical and statistical evidence of homogeneity, we shall be wise not to accept the usual odds of 20 to 1 as indicating a statistically significant difference in behaviour of two groups. We might, for instance, fix an arbitrary limit for the ratio of a difference to its standard error at 3:1, which would give us calculated odds of 369 to 1 against the observed difference being due to chance. These odds, may, of course, be too high, and might lead us to ignore differences that are possibly significant. But if we adopt lower odds we may attach significance to differences that are in fact meaningless. In dealing with observations from the ward, or from the field, where fresh results cannot quickly or easily be collected, it is desirable that attention should be drawn to any points of possible interest or importance, with due emphasis where necessary on the allowance that must be made for sampling errors. In experimental work the case is rather different. The investigator will clearly be wise to take any hint that is offered by his quantitative results; but if he desires to publish his findings and draw conclusions from them, it is reasonable to insist on a stricter standard. There is nothing to prevent his repeating any experiment that has given a statistically dubious answer, and this is clearly what he should do.

Experiments should, indeed, always be repeated, even when a single trial has given a result that passes all the conventional tests of statistical significance. We can never be quite sure that the conditions of a single trial do not include some determining factor other than that we are trying to investigate. By repeating an experiment several times, we are testing, in the only way we can, for the intrusion of unknown factors other than errors of random sampling. If each of several tests gives us a statistically significant answer, and each answer points in the same direction, we shall have some justification for stating our conclusion in general as opposed to particular terms; but if some tests give different answers from others we must solve the problem of why these differences occur before we can accept the indication given by the original experiment.

The question thus arises, assuming a limit to the number of experimental animals that we have available, how we can use them to the best advantage in solving any particular problem. Shall we carry out one, or two, experiments with large numbers of animals in our test and control groups? or, shall we make several experiments, each on a smaller scale?

The answer would seem to be that each test should be made on a number of animals sufficiently large to enable us to detect a difference of the order we are expecting, making allowance for errors of random sampling. When this point has been reached we shall gain more by repeating the experiment, using groups of a similar size, than by doing one very large experiment, in which the effect of sampling errors would be considerably reduced, but which would give us no information in regard to other intrusive factors.

In most laboratory experiments, in which we are expecting a high mortality, usually approaching 100 per cent., in our control group, and are hoping for a much lower mortality, say 30-60 per cent., in our treated group, we shall gain more information by repeating our experiment six times, using 25 animals in each group, than by doing one experiment with 150 animals in each group. The best procedure, in any given case, will depend on the size of the difference we are expecting.

Sometimes, particularly in the application of a therapeutic measure in human disease, quite a small difference in mortality is an objective well worth attaining; and, if we wish to determine a difference of this size, our groups in any individual trial must be relatively large.

Let us suppose we have made an antiserum which, on *a priori* grounds, we expect to be of value in combating a certain infective disease. Like all new curative measures it *must* be subjected to trial before it is adopted for routine use. It is not a question of trial or no trial, but of a well-planned trial that will give us a definite answer as quickly as possible, as against a planless, haphazard series of trials that will take a long while to tell us very little, perhaps at a considerable expense in lives. Let us also suppose that the real average effect of the serum is to reduce the case fatality of the disease from 30 per cent. to 20 per cent.—not, perhaps, a dramatic result but one that will save a large number of patients if the disease is a prevalent one. The only way in which the existence of such an effect can be quickly and certainly established is to test the serum on an adequate group of cases and compare the mortality in this treated group with the mortality in an untreated group. We must ensure that the two groups are as alike as possible by making the comparison over the same period and in the same place, because the infectivity and severity of many diseases fluctuates with time and place; and we shall try, for example, to test only one race, and to have similar age and sex distributions in the two groups.

Table 61 sets out the figures for test groups ranging in size (n) from 10 to 500. In each case the 10 per cent. difference in mortality appears; but the standard error when $n = 10$ is 19 per cent., and though it decreases with increase of n (proportionately, in fact, to \sqrt{n}) it is not until $n = 150$ that the 10 per cent. difference is even twice the standard error. After a trial on two groups each of 200 patients we should begin to think it probable that the serum had done some good; and we might accept the decrease from 30 to 20 per cent. mortality as an approximate estimate of the benefit to be expected from the serum. That is, we save one patient in three of those who would otherwise have died. When trials on this scale were repeated we should be surprised if there were many unfavourable reports. After a trial on two groups of 500 patients we should have no reasonable doubt that our serum had reduced the case fatality.

It is of very real importance that trials of any new therapeutic measure should be planned and carried out on an adequate scale. Otherwise the period of so-called trial may be extended far beyond the necessary limits; and a useless measure

days with a standard error of 0.960 days, whereas the mean time to death of the 28 mice was 5.93 days with a standard error of 0.924 days. The difference is 4.99 days, and the standard error of the difference is $\sqrt{0.960^2 + 0.924^2} = 1.33$. The ratio of the difference to its standard error is $4.99/1.33 = 3.75$, and the odds against observing such a difference as the result of chance (Table 59) are about 2,000 to 1. The conclusion is that we have almost certainly made the disease less acute as the result of immunization, although we have not increased the resistance of our mice to the point at which their chance of ultimate survival is significantly greater.

THE MEASUREMENT OF TOXICITY OR VIRULENCE

We often want to determine the minimal lethal dose of a bacterial toxin, or of a living bacterial culture. Still more often we want to compare the minimal lethal dose of two toxins, or of two cultures. Clearly we must first titrate graded doses of the two cultures against a number of groups of animals. The results of such titrations are instructive. When we divide a large number of similar animals into groups of equal size, and administer to each group one of a series of increasing doses of a lethal culture or toxin, we may observe, if the scale of doses was suitably chosen, that none of the animals dies in the group receiving the smallest dose. With each increase of dose a larger death rate is observed and in the group receiving the largest dose all the animals die.

TABLE 62

Dose <i>a</i> in Arbitrary Units	Percentage Mortality in Groups of 100 Animals	Increase in Percentage Mortality with each Increment of Dose
2	0	—
3	1	1
4	4	3
5	10	6
6	22	12
7	40	18
8	60	20
9	78	18
10	90	12
11	96	6
12	99	3
13	100	1

Table 62 shows a set of hypothetical percentage mortalities in 12 groups of 100 animals, each group being given one of a series of doses of a lethal toxin. Each dose differs by one unit of measure from the preceding dose. When we plot the death rate against dose, as in Fig. 241(A), we obtain a characteristic curve (Table 1927, 1929, 1930) for the toxin, or, more specifically, a dose-response curve. The third column of Table 62 records the values obtained by subtracting the mortality rate for a given dose of *a* units, the mortality for the preceding dose of (*a* - 1) units. Inspection both of column 3 and Fig. 241(A) reveals one of the most important features of the dose-response curve, namely that the rate of change of percentage mortality is greatest in the middle range of the curve. At the extremes, a relatively large change in dose results in a small change in mortality.

of pathogenic bacteria, the dose-response curve is far less steep. The LD50 can be more accurately measured, and even with steep dose-response curves, it is to be preferred to an estimate of the 100 per cent. killing dose. For example, when a strain of *Salmonella typhi-murium* was given in graded doses, each into 25 mice, the rise in mortality with numbers of bacilli injected was as follows: 10 bacilli, 24 per cent.; 10^3 bacilli, 56 per cent.; 10^5 bacilli, 88 per cent., and 10^7 bacilli, 96 per cent. For 100-fold increases in dose the change in percentage mortality in the region of 95 per cent. was relatively small; it was greater in the region of the 50 per cent. killing dose. In essentials, then, toxicity or virulence is best measured in terms of the LD50.

It is instructive to inquire why the dose-response curve has this particular S-shape. If we assume that each group of 100 animals is representative of the total of 1,200 animals from which they were drawn, it is clear that the figures in column 3 of Table 62 represent the proportion of all the animals which are susceptible to a dose of a units, but not to a dose of $(a - 1)$ units. In each case, then, we may say that the recorded proportion of animals is on the average susceptible to a dose half-way between these two values, that is, $(a - 0.5)$ units. Thus, the 3 per cent. of the animals susceptible to 4 units but not to 3 units, are on the average susceptible to 3.5 units, and so forth. Plotting these proportions against doses as abscissæ we obtain the curve in Fig. 241 (C), which is in effect a frequency distribution of susceptibilities in the population of animals employed. The average, or mean resistance, corresponds to the LD50. The hypothetical curve B represents the response of another batch of animals to the toxin, estimated from a series of doses increasing by 0.4 unit. The curve (D), the distribution of susceptibilities derived from it, has been drawn on a scale of unit increases in dose, for comparison with the curve (C). It is clear that the steeper dose-response curve corresponds to a narrow distribution of susceptibilities obtained in the performance of the test. These distributions, it should be noted, are distinct from the distributions of chance effects discussed on p. 1120, which were derived from an ideal population of identical animals infected with a fixed dose. Here we are estimating how widely the population of animals varies in resistance to graded doses, though each mortality measurement is subject to the error discussed above. In estimating the mortalities from which the dose-response curve is built, we shall have to take into account both sources of error—the error due to heterogeneity of the animal population tested, and the error due to chance effects in small groups of animals. When the death-rate of a group is known, the last can be estimated by the \sqrt{npq} formula; the first, only by measuring the slope of the dose-response curve.

It will be clear that the more homogeneous the animals used, the more they approximate to an ideal test reagent and the smaller the error of measurement with a group of animals of a given size. Some breeds of laboratory animals used for biological assay of this kind are grossly heterogeneous, but it is possible to reduce the heterogeneity by inbreeding of selected strains. These inbred strains, which may or may not be pure lines, often yield much steeper dose-response curves than those of the parent strains, and their use in biological assay permits either a greater increase in the accuracy of an assay for the expenditure of the same number of animals, or measurements of the same accuracy with smaller numbers of animals. For example, Prigge (1937) recorded that the ratio of the smallest to the largest dose of diphtheria toxoid required to immunize the individual animals in a mixed laboratory strain of guinea-pigs against a standard injection of toxin was 1 : 32,000. Similar tests of pure-line strains inbred by brother-sister matings revealed a strain for which the ratio was as small as 1 : 25.

The LD50 may be estimated directly from a dose-response curve. One simple method is to fit a straight line to observed mortalities whose values lie between 25 per cent. and 75 per cent. and read off the LD50. Its accuracy depends on the assumption that the curve is approximately a straight line between these limits. It is limited in that

100 times more virulent than strain 18; whereas, as this experiment showed, there would have been no adequate reason to assume any difference in virulence.

THE MEASUREMENT OF IMMUNIZING POTENCY

We have already emphasized (p 1125) that the species of animal and of bacterium we use for immunological tests vary not only from day to day within a given laboratory, but from laboratory to laboratory. It follows that, strictly speaking, many of the results of a test are valid only for the particular biological system—such as mice and *Str. pneumoniae*—used on that occasion. By using mice of a known and obtainable breed and keeping them on defined diets, etc., and by using a known strain of pneumococcus whose constant virulence is assumed, say, by animal passage or preservation in the freeze-dried state, we may attempt to specify the conditions under which we, or other investigators, may expect to repeat our results. But the variability and heterogeneity of biological systems as complex as whole animals reacting with a living pathogen are quite beyond exact specification, and all we can hope to achieve is a broad similarity of circumstances, from the exploitation of which we shall arrive at approximately the same conclusion as before. When, however, such tests are made in order to specify an immunological product like a vaccine or an antitoxin for human use, the range of unpredictable variation within biological test systems may be so large that the answer we get from it is clinically unreliable. Suppose we are testing the immunizing potency of diphtheria toxoid on an apparently average batch of guinea-pigs. If in fact the animals were exceptionally easy to immunize, we should overestimate the potency of a given weight of the toxoid; and we should underestimate it with guinea-pigs of more than average resistance to immunization. Diphtheria toxoid happens to be relatively harmless in large doses, so that in this instance we can allow for overestimation of potency by immunizing with plenty of toxoid. This will mean that very large amounts of an underestimated toxoid may be unwittingly injected, which is wasteful, but not dangerous. With more toxic substances, obviously we cannot risk making such allowances for overestimated potency. Moreover, the allowances we make are in all cases largely guess-work. For these reasons this method of direct estimation of potency from the magnitude of the response in the test animal is to be avoided whenever possible. Fortunately we can often eliminate some of the uncertainty about the reproducibility of the biological test system by introducing standard preparations of the active substance

THE HISTORY AND DEVELOPMENT OF BACTERIOLOGY¹

Bacteriology illustrates, perhaps better than any other branch of biology, the complex system of interrelationships among the sciences. Since the microorganisms are so small that they are invisible not only to the naked eye but to the eye aided by simple lenses, their very discovery necessarily depended upon the development of optical science to such a point that lenses of sufficient perfection and magnifying powers became available. It is not strange, therefore, that the many evidences of bacterial activity, such as the putrefaction and decay of organic matter, the infectious diseases of man and lower animals, the common fermentations and similar natural phenomena, should have been viewed in the past as semimetaphysical processes. Despite the entire lack of evidence, some of the older writers voiced a belief in the existence of such microorganisms. Fracastorius of Verona (1546) suggested a *contagium vivum* as a cause of disease, and von Plenciz (1762) accounted for the specificity of disease on the basis of microbic etiology. Although such speculations might be considered a result of prophetic insight, in all probability they were no more than guesses to which, in view of present knowledge, it is not difficult to ascribe significance. In the absence of the experimental approach, the fertility of philosophic speculation remains a doubtful quality.

Kircher had reported the observation of "minute worms" in the blood of plague patients in 1659, but it is doubtful that he ever saw the plague bacilli. The first concrete foundations of bacteriology were laid by a Dutchman, Antonj van Leeuwenhoek, in the latter part of the seventeenth and the early part of the eighteenth centuries. Leeuwenhoek, a man of indefatigable industry and great curiosity, held a political sinecure in his native town of Delft. In his odd time, of which he apparently had a good deal, he ground lenses and became the most skilful lens grinder of his time. He utilized these lenses in the construction of simple microscopes and spent many years of his long life (1632-1723) in examining a great variety of natural objects, with unremitting industry if without system, and in the course of his observations chanced to come across the organisms now known as bacteria. That he did in fact observe these creatures is evident from the drawings he left of them. In a communication to the Royal Society,² of which he was a member, he states,

¹ For details see Bulloch: *The History of Bacteriology*. Oxford University Press, New York, 1938.

Observations, communicated to the publisher by Mr. Antony van Leeuwenhoek, in a Dutch letter of the 9th of Octob. 1676, Here English'd Concerning little animals observed by him in rain- well sea and snow water, as also in water wherein pepper had lain infused

obtained by comparing doses of serum that protected mice against the same challenge dose of *Salm. typhi* was 2 : 1 ; but by the less valid, but nevertheless often used, method of comparing the challenge doses of bacteria required to produce the same mortality rate in mice protected by the same volume of the two sera, the potency ratio was 29 : 1.

We can express the ratio (potency of "unknown" : potency of standard) directly, saying, for example, that, weight for weight, the unknown is 0.03, or 40.0, times the activity of the standard. It is more usual to assign unit potency

TABLE 64

SHOWING THE IMMUNOLOGICAL SUBSTANCES RECOGNIZED INTERNATIONALLY AS BIOLOGICAL STANDARDS OR REFERENCE PREPARATIONS.

International Standards.	Weight of the Preparations with Unit Potency.
Diphtheria antitoxin	0.0028 mgm.
Diphtheria toxoid, plain	(No unit defined)
Tetanus antitoxin	0.3094 mgm.
Tetanus toxoid	0.0300 mgm.
Gas gangrene antitoxin (<i>perfringens</i>)	0.1135 mgm.
Gas gangrene antitoxin (<i>oedematiens</i>)	0.1135 mgm.
Gas gangrene antitoxin (<i>histolyticum</i>)	0.2000 mgm.
Gas gangrene antitoxin (<i>Vibrio septique</i>)	0.0974 mgm.
Gas gangrene antitoxin (<i>Sordelli</i>)	0.1334 mgm.
Staphylococcus alpha antitoxin	0.2376 mgm.
Staphylococcus beta antitoxin	2.6230 mgm.
Anti-dysentery serum (<i>Shiga</i>)	0.0500 mgm.
Anti-pneumococcus serum (Type I)	0.0886 mgm.
Anti-pneumococcus serum (Type II)	0.0894 mgm.
Anti-A blood grouping sera	0.3465 mgm.
Anti-B blood grouping sera	0.3520 mgm.
Old Tuberculin	0.0100 mgm.
Mammalian P.P.D. (purified protein derivative)	0.000028 mgm.
Anti-typhoid serum	No units defined
Scarlet fever (<i>streptococcus</i>) antitoxin	0.049 mgm.
Anti- <i>Brucella abortus</i> antiserum	0.091 mgm.
Anti-Q Fever serum	(No unit defined)
International Reference Preparations.

to a certain weight or volume of the standard, and express potencies as so many units per ml. or per gm. Thus the solution of the international standard for diphtheria antitoxin, as issued for use, contains 10 units per ml. If the ratio of equipotent volumes of standard and unknown proves to be 0.025, then the unknown contains $10/0.025 = 400$ units per ml.

The refinements of potency comparisons that lead to results exemplified in Fig. 242 are not always practised in immunological work. As we noted on page 1131, the dose response to exotoxins is steep, so that the interval between the maximum ineffective dose and the minimum fully effective dose, even when

"Having several times endeavoured to discover the cause of the pungency of pepper upon our tongue, and the rather, because it hath been found, that though pepper had layn a whole year in vinegar, yet it retained still its pungency, I did put about $\frac{1}{3}$ of an ounce of whole pepper in water, placing it in my study, with this design, that the pepper thereby being rendered soft, I might be enabled the better to observe what I proposed to myself. This pepper having lain about three weeks in the water, to which I had added some snow water, the other water being in great part exhaled, I looked upon it the 24th of April, 1676 and discern'd in it, to my great wonder, an incredible number of little animals, of divers kinds, . . . The 4th sort of creatures, which moved through the three former sorts, were incredibly small and so small in my eye, that I judge, that if 100 of them lay one by another, they would not equal the length of a grain of coarse sand; and according to this estimate, ten hundred thousand of them could not equal the dimensions of a grain of such sand." Leeuwenhoek is known to have used only simple lenses, and the highest magnification he reached was approximately 300 diameters. Probably he did not observe objects as small as bacteria by transmitted light. He kept his method of illumination secret; it is not improbable that he used reflected light, similar to that used in present day ultramicroscopes. Although his observations did not lead to an immediate development of bacteriology, their significance was apparent to many of the scientific men of the day. Slare, in a comment on a report³ on an epidemic among cattle, concludes with the remark, "I wish Mr. Leeuwenhoeck had been present at some of the dissections of these infected Animals, I am perswaded he would have discovered some strange Insect or other in them."

Nearly a century later, in 1786, the Danish zoologist, O. F. Muller, studied these microorganisms and succeeded in discovering many structural details of which his predecessors had been ignorant. He depicted several kinds of bacteria so accurately that they can be identified today as belonging to one or another of the chief divisions.

Another unequivocal advance was made by Ehrenberg (1795-1876). His principal work upon the "infusion animals" or "Infusionstierchen," as these organisms were then termed, was published in 1838 and brought together much more definite and detailed information concerning bacteria than had been previously secured. The chief merit of Ehrenberg's work lay in the system that it introduced into the study of microorganisms. He was able to establish a number of different groups among the organisms now known as bacteria, and recognized clearly the fundamental differences between the larger forms, such as the screw-shaped or spirally-twisted organisms, and certain of the true protozoa with which they had heretofore been classed. Some of the names which Ehrenberg conferred upon his "infusion animals," such as bacterium and spirillum, are still current in bacteriological nomenclature, although with changed signification.

³ Phil. Trans. Roy. Soc., 1682, 13 93. An abstract of a letter from Dr. Wincler, chief physician of the Prince Palatine, Dat. Dec. 22 1682 to Dr. Fred Slare, Fellow of the Royal Society, containing an account of a Murren in Switzerland, and the method of its cure. A further confirmation of the above mentioned Contagion, of its nature, and manner of spreading by way of Postscript from the ingenious Fred Slare, M. D. and F. R. S., Dat. March 27, 1683

should lead us to overestimate the support that a statistically significant result can give to the particular hypothesis the experiment was intended to test. As Fisher (1950a) points out, all that a properly designed experiment can test is the "null hypothesis"; that is, the hypothesis that there is no difference between the control and test systems that we are studying. If, for example, the calculated odds prove to be 3 to 1 against a chance effect in the defined conditions of a therapeutic test of a fluid A in a fatal bacterial infection, *no one could decide, without further experiment, whether the effect observed was due to "chance" or to A.* If the odds prove to be 1,000 to 1, we can say that the effect is unlikely to be an example of a chance variation of the kind we expect from the materials used in the test; but we cannot say that it was *therefore* due to the administration of a few millilitres of the fluid A. The statistically significant result indicates that the test and control groups differ in some important respect and therefore permits us to consider the fluid A as a possible cause of that difference; but the decision that A is the cause of the observed reduction in mortality in the test group is independent of any statistical demonstration of significance, and in a final analysis depends on the experimenter's knowledge of his particular science and his appreciation of the consistency of his ideas of A's action with the general theory of that science. If A was in fact water, the conclusion, no matter how statistically significant the experimental result, that a small quantity of water had cured the infection, would rightly be considered as suspect. If A, on the other hand, was a solution of a substance known to be antibacterial and non-toxic to the animals used in the experiment, then these pieces of scientific knowledge, coupled with the disproof of the null hypothesis, would go far towards justifying the conclusion that A was capable of curing a particular type of infection.

The aim, then, of the statistical method in experiments involving the comparison of two or more groups of events is to discover the probability that the null hypothesis is untrue; and only in those cases where the null hypothesis is disproved is there any justification for considering the possibility that an observed effect resulted from any of the deliberate variations in the conditions of the experiment.

The proper design and analysis of quantitative tests is essential for the efficient practice of a science. That the record of immunological work in the past contains few examples of statistical analysis is no proof that such analysis is unnecessary. Sometimes the results of an experiment are so clear cut that any arithmetical analysis is unnecessary; on many other occasions it will be found that the data are incapable of supporting the conclusions reached by the investigators. There is no doubt that much of value has been learned without any consideration of statistical design, but it is justifiable to suppose that the knowledge could often have been achieved with a great deal less expenditure of time and materials had the experiments been designed more efficiently.

The voyager who ignores tidal streams and compass deviations will arrive somewhere in the long run; but he is less likely to identify correctly the place at which he has arrived than is another who allows for these variables by the accepted methods of elementary navigation.

In the two or three decades succeeding Ehrenberg's work, considerable knowledge was amassed concerning the mode of development and physiology of bacteria, as well as their position in biological classification, but the labors of Dujardin, Perty, Cohn, Nageli and others, although important, are quite overshadowed by the work of Louis Pasteur (1822-1895).

Up to the period of Pasteur's investigations, the role played by bacteria in various familiar natural processes, such as putrefaction, decay and fermentation, had been, perhaps, vaguely suspected, but had not received conclusive demonstration. Pasteur, originally trained as a chemist, had done his early work on stereoisomerism. The formation of optically active amyl alcohol during the course of the lactic acid fermentation attracted him to the study of the

Fig. 1. The first pictorial representation of bacteria. Reproduced from *Arcana Naturae delecta ab Antonio van Leeuwenhoek*. Delphis Batavorum apud Henricum Crooneveld. 1695.

fermentation processes. The demonstration of the plant-like nature of yeast by Caignard-Latour and by Schwann, together with the asymmetric synthesis of amyl alcohol, led him to suspect that fermentation was a result of the activity of living cells. This view was strongly opposed by the chemists of the day, Liebig, Berzelius and Wohler in particular, who regarded the presence of dead and dying yeast cells of importance only in that in the course of their own molecular disintegration they toppled over and dragged down certain complex organic molecules with which they were in contact. Pasteur's researches led him deeper into the morass of fundamental biology than, perhaps, he had anticipated, for, before the essentially biological basis of fermentation could be conclusively demonstrated, the problem of spontaneous generation of life from decomposing organic materials presented itself for solution.

CHAPTER 44

THE MECHANISMS OF BACTERIAL INFECTION

BEFORE we can discuss the mechanisms by which the host resists infection, we need as clear a picture as possible of the ways in which the parasite injures the host. Some parts of the picture are confused, others sketchy; but parts of the main outline are quite clear and definite, and it is with these that we shall be mainly concerned.

Specific Infection. Koch's Postulates.—

Although not immediately pertinent to our main problem, a brief discussion of the kind of evidence which will justify the conclusion that a particular disease is caused by a particular parasite forms a convenient introduction to infective processes in general, and raises points of some importance.

A number of conditions which must be fulfilled in order to establish such a causal relationship are set out in most bacteriological textbooks under the title of "Koch's Postulates," though Koch (1891) did not enunciate them in the categorical form in which they are usually quoted. They run in general terms as follows:

- (1) The organism should be found in all cases of the disease in question, and its distribution in the body should be in accordance with the lesions observed.
- (2) The organism should be cultivated outside the body of the host, in pure culture, for several generations.
- (3) The organism so isolated should reproduce the disease in other susceptible animals.

To-day we recognize additional criteria of a causal relation between a micro-organism and a disease, of which one of the most valuable is the demonstration of specific antibodies in abnormally large amounts in the blood of an infected man or animal, or an abnormally high degree of specific immunity to the infecting agent in a recently recovered animal.

It is obvious that technical difficulties may prevent us from fulfilling all Koch's postulates in every disease. We may be unable to cultivate the causative parasite although we can demonstrate its constant presence in the lesions by suitable staining methods; this has hitherto been the case with regard to the bacillus of leprosy. The organism may be so small, and its morphology so doubtful, that we are unable to demonstrate its presence in the tissues, or to distinguish it with certainty from other bodies of the same order of size. When we cannot cultivate the organism *in vitro*, we may, as in the initial studies on most virus infections, have to rely on the third postulate alone, and reproduce the disease in a suitable animal by the inoculation of filtrates from infected blood or tissue extracts that contain no visible or cultivable bacteria. In other cases the third postulate may be our stumbling-block. We may be able to relate a characteristic bacterium to the

For a great many years it had been generally held that living things, even organisms as large and complex as mice, were spontaneously generated during the course of the decomposition of organic substances. The experiments of the poet physician Redi (1626-1697), however, indicated definitely that maggots were not spontaneously formed from decomposing meat but were in fact fly larvae hatched from eggs deposited in the meat by flies. Spallanzani, an Italian monk, showed further that putrescible meat infusions, when properly heated, did not spoil and did not contain living organisms even though kept over long periods of time. Needham, an Irish priest, took issue with Spallanzani on the basis of similar experiments in which spoilage took place and living organisms appeared in spite of previous heating. A second series of elaborate experiments by Spallanzani corroborated his earlier findings and indicated the fallacies in Needham's experiments. Other experiments by Schulze, Schwann, Schroder and von Dusch indicated that no spontaneous generation took place but rather that the source of living organisms was the air in which they were suspended, a conclusion amply confirmed by the careful experiments of the Englishman Tyndall. The entire controversy was revived by the extended experimental work of Pouchet, which appeared to indicate a spontaneous generation of microorganisms in heated organic materials; and Pouchet created a great stir in French scientific circles—a stir in which Pasteur found himself.

The point at issue was, obviously, whether spoilage of such infusions took place as a result of the presence of microorganisms or whether the appearance of living organisms was a result of the decomposition—a general question of which the question of the biological basis of fermentation was a special case. Pasteur's extended and careful investigations showed beyond reasonable doubt that microorganisms were present in air, the numbers varying with the place from which the air came; that putrescible material which had been heated sufficiently to destroy all life would keep indefinitely with no evidences of either decomposition or the presence of living organisms, and, finally, that a common source of contamination of such sterilized material was air in which living microorganisms were suspended.

The fact that life came only from life (biogenesis) and was not spontaneously generated from non-living materials (abiogenesis) having been established,⁴ it was not difficult to prove that fermentations resulted from the physiological activities of living, growing microorganisms. Furthermore, the specificity of fermentations, the fact that different kinds of fermentations were consequences of the activities of different kinds of microorganisms, grew out of this work. The transition from studies on fermentation to studies on infectious disease was not a difficult one to make, for there was a growing awareness among scientific men of the day of the similarities between the development of disease in an individual and the fermentation of sugar solutions.

Pasteur was led into a study of the "diseases" of beer and wine, processes which he found to be none other than secondary fermentations brought about through the activities of extraneous microorganisms, decompositions that resulted in the accumulation of end products of an undesirable nature. He

⁴ Speaking scientifically. Philosophic speculation is beyond the scope of the present volume.

There are two distinct stages in the use of experimental animals in the study of an infective disease. In the first, as demanded by Koch's third postulate, we are trying to reproduce a particular infection in a form which is clinically or pathologically recognizable as identical with the natural disease. In the second we are using our susceptible animal for an intensive study of this infective process. The lesions produced in the guinea-pig by the subcutaneous inoculation of cultures or filtrates of the diphtheria bacillus bear little resemblance to diphtheria as it appears in man; but almost the whole of our present knowledge of immunity in relation to that disease, which has at last placed us in a position to exert effective control, has been built up on knowledge gained from experiments on that small laboratory animal.

It should be noted, also, that there is a shifting of emphasis from the clinical to the bacteriological side as our knowledge progresses. At the start of our inquiry we are presented with a clinical or epidemiological phenomenon, and our task is to discover the microbial parasite that is the necessary cause. We may, as in the case of diphtheria, or syphilis, or tetanus, find that a single specific parasite is responsible; indeed this is far the most frequent solution if we neglect racial variations within the causative microbial species. We may, however, find that a disease characterized by one clinical syndrome may be caused by one of several distinct species of bacteria. Secondary pneumonia affords one example, bacillary dysentery another. Once the connection between a particular parasite and a particular disease has been firmly established, the tendency of the bacteriologist is to focus his attention on the organism, rather than on the clinical condition to which it most frequently gives rise, and to try to build up a picture of the reactions between that organism and a susceptible host species in general. Thus we should think in terms of pneumococcal infection, rather than in terms of pneumonia; and regard that particular condition merely as one example of the reaction between the pneumococcus and the human tissues, including in our generalized picture such lesions as middle-ear disease, sinusitis, meningitis, peritonitis, suppurative arthritis, etc., and keeping constantly in mind the part played by bacteræmic spread and selective localization.

It will be convenient, in this and the immediately succeeding chapters, to deal exclusively with bacterial infections, since most of our knowledge has been acquired in studying infections of this type. In a later chapter we shall discuss how far our conceptions have to be modified in the case of infections with the filtrable viruses. Protozoal and helminthic infections are beyond the scope of this book; though the methods elaborated by the bacteriologist are proving fruitful in their application to this wider field.

Invasion of the Tissues by Bacteria.

With very few exceptions, bacteria and other microbial parasites must gain access to the host's tissues and multiply in them before they can produce any harmful effect; and we may for the moment regard the capacity to pass through some protective covering layer—most commonly through one of the mucous surfaces of the body—and to multiply in the subjacent tissues, as an essential attribute of a pathogenic organism. The "passing through" must not, of course, be interpreted too literally, or as necessarily implying any active motion on the part of the parasite. Apart from gross mechanical injuries to the skin and mucous membranes, the routes by which micro-organisms and inert particles of non-living matter get into

controlled the fermentative process by gentle heating followed by inoculation of the fermentable mixture with microorganisms which brought about the desired type of decomposition. The heating process has been termed "pasteurization" in his honor. A further development was a study undertaken at the request of the silk growers, of pébrine, a disease of silk worms which was assuming considerable economic importance. Here too a microbic etiology was discovered and practical control measures could be and were applied.

The so-called germ theory of disease had, at this time, permeated more and more generally into the scientific thought of the day, largely, perhaps, as a result of the strong support it received from Pasteur's researches on fermentation. Lister (1827-1912), an English surgeon, was one of the first to grasp the significance of Pasteur's work in relation to human disease, and put the new concepts into practical operation with his introduction of the antiseptic technique into surgical operations. The free use of strong carbolic acid brought about a marked decline in surgical mortality, which had been terrifically high in even the most minor operations. It remained, however, for Robert Koch (1843-1910), a German physician, to develop the experimental methods necessary to the proof of the causal relation between bacteria and infectious disease.

One of the greatest difficulties encountered by the early workers in bacteriology was that of separating bacteria from one another. That morphologically different types existed was clear, and, further, that organisms exhibiting the same morphology differed from one another in ability to produce disease had been apparent from the early work on pyemia. Perhaps one of the greatest single contributions to bacteriology is the method of isolation of bacteria in pure culture developed by Koch. It consisted, essentially, of culture on a semisolid medium, a nutrient environment solidified by the addition of gelatin or agar-agar—a method so simple and yet so effective that it is used practically unchanged today (p. 20). Koch had achieved what he had said only a year or two before was "impossible."

Although it was almost entirely through the works of Pasteur that bacteria and other microorganisms emerged from their relative obscurity as organisms of interest chiefly to the professional biologist and took a conspicuous position in natural science as a group of organisms whose activities and capabilities were full of a far-reaching significance for all mankind, the contributions of Koch and the German school were also of fundamental significance. If any one man can be looked upon as the founder of bacteriology, that man is Louis Pasteur. Likewise, the infant science owed its firm experimental foundation directly to Koch, a foundation without which it could never have become a science.

The isolation of bacteria in pure culture, coupled with the methods of staining developed by Koch, Ehrlich, Wiegert and others, so markedly stimulated the study of bacteriology that the ensuing decade or two, the eighties and nineties, became in truth the first golden age of that science. As the history of all science is, in essence, the history of its methodology, so in bacteriology discovery of the specific etiology of a variety of infectious diseases followed rapidly upon Koch's studies of anthrax and his isolation of the anthrax bacillus. Koch himself isolated and described the tubercle bacillus in 1882 and the cholera

the parasite and the resistance of the host. A highly virulent strain may in a resistant host produce a disease indistinguishable from that due to a strain of low virulence in a susceptible host. When we talk of virulence, either the host and its condition is specified, or we imply "virulent" in a species of host of average resistance. If we do not, any comparisons of virulence are meaningless. The same is true of statements about host resistance: a train of parasite is specified, or a parasite of average virulence is implied.

It may, then, be stated that multiplication of bacterial cells within the tissues is one of the essential factors on which infection depends. Some species can produce a fatal infection without any wide dissemination within the body: others cause death only when such widespread dissemination occurs. A part of the mechanism of resistance will clearly be concerned with the killing and removal of the bacterial cells as such.

Bacterial Localization.

Apart from the generalized bacteremic invasion referred to above, most bacteria tend to lodge and multiply in tissues remote from their primary lodgment; and certain species, or groups of species, differ sharply from one another in the site of such localization.

The site of the primary lodgment and the direction of the initial spread of infection are largely determined by the portal of entry to the body, and by the local anatomy, particularly by the direction of the lymph flow. But the portal of entry in its turn is determined by the natural habitat of the parasite, and this by its potentialities for life under different environmental conditions.

Thus, some species of staphylococci are normal inhabitants of the skin. Those species, or races, that are potentially pathogenic, may gain access to the underlying tissues by the hair follicles, or by the ducts of the sebaceous glands, and cause the characteristic pustules or boils.

Many of the bacteria that lead a parasitic existence in the nasopharynx, and are spread from host to host in droplets, droplet-nuclei and dust, tend in consequence of a common respiratory portal of entry to show a rough similarity in the distribution of the lesions they produce; but the similarity is very incomplete, and breaks down altogether on a close analysis. Thus, pneumococci, hæmolytic streptococci, influenza bacilli, diphtheria bacilli and meningococci are all spread in this manner. Diphtheria bacilli and hæmolytic streptococci both tend to lodge and multiply in the tonsils, the former giving rise to the characteristic lesions of faucial diphtheria, the latter to tonsillitis. Both produce soluble toxins, which diffuse widely from the initial lesion. But the tendency to invasive spread is much greater in the case of the streptococcus than in that of the diphtheria bacillus. Pneumococci, hæmolytic streptococci and influenza bacilli may all spread to the lungs and cause pneumonic lesions, but they do it in very different ways. The pneumococcus fully merits its name by its pre-eminence as an invader of the pulmonary tissue. It is the sole important bacterial agent in the primary pneumonia of adolescence and adult life. In the secondary pneumonias associated with such infections as measles, whooping cough and influenza, it shares its honours with the influenza bacillus and the hæmolytic streptococcus. The meningococcus, although it is a nasopharyngeal parasite and spreads by droplet infection, produces its characteristic lesions in the meninges. Pneumococci, hæmolytic streptococci and influenza bacilli may also give rise to meningitis; but whereas this is the modal reaction of the meningococcus when it produces clinically obvious infection, it is

vibrio the following year. Other discoveries tumbled in one after another with bewildering rapidity. Klebs described the diphtheria bacillus in 1883, and in 1884 Löffler isolated and studied this organism; Fraenkel discovered the pneumococcus in 1886, and the following year Weichselbaum isolated the meningococcus; Kitasato cultivated the tetanus bacillus in 1889, and in 1894 he and Yersin discovered the plague bacillus independently. These and many other similar discoveries made clear to the world in a striking fashion the significant implications of the new science.

Meanwhile, the investigations of the French workers had taken a somewhat different turn. Many years before, in 1796, Jenner, an English physician, observed that infection of human beings with cowpox, a disease of cattle closely resembling smallpox, protected against subsequent infection with smallpox. Pasteur, investigating first chicken cholera and later anthrax and swine erysipelas, succeeded in demonstrating a basic principle of immunology, that inoculation with attenuated microorganisms, those which by some sort of treatment had lost their virulence, resulted in the development of an increased resistance or immunity of the inoculated individual against later infection with the same organism. Pasteur's most striking application of this principle was in the development of a prophylactic treatment against rabies—an accomplishment with some elements of the dramatic because of the dread in which the disease was held. Not long afterward the American workers, Salmon and Theobald Smith, discovered that the inoculation of killed bacteria would also stimulate the development of the immune state. The cellular theory of immunity propounded by the Russian zoologist, Metchnikoff, was soon overshadowed by the discovery of tetanus antitoxin by von Behring and Kitasato and, shortly afterward, the discovery of diphtheria antitoxin by von Behring, and the precise studies of the humoral antibodies by Bordet and others; only in recent years has it come into its own. The utilization of the immune phenomena in the diagnosis of disease by Wassermann, Widal and others, Paul Ehrlich's development of his side-chain theory of immunity and his initiation of chemotherapy through the synthesis of salvarsan all contributed to the expansion and development of bacteriology. The discovery of the filterable viruses, apparently living agents too small to be seen with the most powerful microscopes, by Iwanowski, Beijerinck, and Löffler and Frosch brought up new problems, many of which are still unsolved today.

The new science, sired by Pasteur and nurtured by Koch, expanded beyond medicine and infectious disease into agriculture and the industrial fields. The genius of the Russian worker, Winogradsky, made possible the elucidation of the perplexing problems of soil fertility by his isolation of autotrophic bacteria which oxidized ammonia to nitrites and nitrates. The discovery of the nitrogen-fixing bacteria living symbiotically with leguminous plants by Hellriegel and Wilfarth and of the free-living nitrogen-fixing forms by Winogradsky and by Beijerinck further clarified the puzzles of soil fertility and indicated the important functions of the soil bacteria. The discovery of the bacterial etiology of pear blight by Burrill and the isolation of bacteria responsible for many other diseases of plants have shed new light on old agricultural problems. It has also been discovered that other kinds of bacteria impart the characteristic flavors or aromas to butter, cheese and other dairy products; and that still

competent histologist could distinguish them without bacteriological assistance. The special case of tuberculosis is of particular interest, in that a beginning has been made in tracing the connection between the various chemical products of the bacterial cell and the type of tissue reactions to which they give rise (see p. 496). Another example is the non-toxic, non-antigenic lipid isolation from *Erysipelothrix monocytogenes* by Stanley (1919), which induces in rabbits the monocytosis that characterizes the natural infection by this organism.

It is not, of course, true that every pathogenic bacterium provokes a distinct and characteristic cellular response, or that the pathologist unaided can often arrive at an exact bacteriological diagnosis from a histological examination of the infected tissue; but, as Kettle (1927) has pointed out so clearly, there is a broad correlation between certain types of lesion and certain groups of bacteria; and the groups which the pathologist would recognize on the basis of the distribution and type of the lesions produced are, in many cases at least, those which the bacteriologist would recognize as containing closely related bacterial species.

All this is perhaps obvious and elementary; but it is of the first importance to realize that different pathogenic parasites have different points of attack, and different methods of attacking.

Bacterial Characters Associated with Pathogenicity.

There is no apparent reason why the mere presence in the tissues, or blood stream, of any reasonable number of cells of an order of size expressed in low multiples of μ should exert any harmful effect on the host that harbours them. No mechanical theory of the pathogenic action of bacteria is compatible with our knowledge of the way in which the tissues deal with inert particles which have gained access to them. The basis of all harmful effects of bacterial infection is quite certainly chemical; and only when the chemist has replaced the immunologist shall we be able to give an intellectually satisfying account of what happens when a particular parasite invades a particular host. In the meantime we must do what we can with the crude data at our disposal.

It has long been known that certain bacterial species produce highly poisonous substances which give rise to characteristic lesions or symptoms when injected into susceptible animals. These are the bacterial toxins. Besides these obvious toxins, less toxic substances are found in the bacterial bodies, and among the soluble products of bacterial growth, which act on tissues or tissue constituents and which may directly intoxicate the infected host, or play an auxiliary part in promoting invasion.

It is fairly easy to establish the pathogenic rôle of a frank bacterial toxin, especially when it is antigenic. Taking the toxin of *Cl. tetani* as an example, we find that: (a) it is produced by the tetanus bacillus during an infection, because the body responds by producing specific antibody; (b) virulence and toxigenicity are associated since virulent strains of *Cl. tetani* produce the toxin, whereas avirulent strains do not; (c) injection of toxin alone mimics the natural disease; (d) active immunization with toxin protects against tetanus; and (e) antitoxin passively immunizes against tetanus.

When the substance produces no characteristic intoxication, or is not toxic although suspected of having an auxiliary rôle in infection, evidence of the kind in (a) and (b) is not conclusive, because the body responds to all bacterial antigens, irrespective of their pathogenic rôle; and the association of a substance with the

others determine the success or failure of various industrial processes, such as the retting of flax, the tanning of hides and, perhaps, the curing of tobacco.

Thus, in the space of only a few decades, bacteriology had become a full-blown, vigorous young science, fully capable of standing on its own feet—and this from Leeuwenhoek's "little animals" that behaved in such curious ways.

The outstanding success of the practical applications of bacteriology should not be allowed to overshadow the fact that it owes its present important place among the biological sciences quite as much to its general scientific significance. It has been often pointed out that bacteriology has produced a change in man's conceptions of the world around him so sweeping as almost to deserve the term "revolutionary." Up to the middle of the nineteenth century the character of many of the most familiar natural processes, such as decay, fermentation and the like, was entirely misunderstood, contemporary spontaneous generation of at least the lower forms of life was the generally accepted belief of most scientific men, infectious diseases were not sharply differentiated from one another and the most fantastic hypotheses were advanced to explain their existence. Although the great mass of material phenomena elsewhere had been brought into apparent orderliness and system, here was a region in which the unscientific imagination rioted in mystery and extravagance. The penetration of this realm of obscurity by the discoveries of bacteriology gave the human race for the first time in its history a rational theory of disease, dispelled the myths of spontaneous generation, and set the process of decay and kindred phenomena in their true relation to the great cycle of living and non-living matter. The new conception of the microscopical underworld which bacteriology brought into biological science must be reckoned as a conspicuous landmark, and, in so far as it has changed the attitude of man toward the universe, should be regarded as one of the most important triumphs of natural science.

Underlying all the applications of bacteriology are certain fundamental facts and principles concerning the structure, mode of development, and general physiologic requirements and capabilities of bacteria themselves. This subject matter constitutes the ground work of bacteriology, and is essential not only to a proper comprehension of the present practical applications of bacteriology, but also to the further development of the science.

endotoxin is of the order of 5-25 mgm. for mice—an enormous dose compared with the corresponding figure (see above) of 0.0016 μ gm. for botulinum toxin. They are relatively stable, withstanding temperatures of 100° C. for over 1 hour.

Finally, endotoxins are seldom strongly antitoxinogenic, though they may stimulate a good agglutinin, precipitin or protective antibody response. With some organisms it has proved impossible to prepare anti-endotoxic sera. More commonly prolonged immunization of an animal yields an antiserum which is able to neutralize a few M.L.D. of the endotoxin; but the simple linear relationship between the amount of toxin and antitoxin in a just neutralized mixture that obtains with exotoxins does not hold with endotoxins. Often no amount of increase in antitoxin affords protection when the dose of endotoxin passes a certain limit.

Although this broad distinction can be made by comparing typical exotoxins with typical endotoxins, not all toxins fall simply into two well-defined groups. Thus, the toxin of *Cl. botulinum* is relatively heat-resistant (75°-80° C. for 10 min.); so is the exotoxin of *Sh. dysenteriae* (Anderson *et al.* 1945). The α -toxin of *Cl. welchii* has a relatively large L.D 50, and is relatively heat-resistant (70° C. for 30 min.). The erythema-producing toxin of the hæmolytic streptococcus—the toxin which is responsible for the rash in scarlet fever, and is employed in the Dick reaction—is filtrable, has a characteristic action on the skin of a susceptible person, and is antitoxinogenic; but it is relatively non-toxic to laboratory animals. It is described both as heat-labile (Stock 1942) and heat-stable (Hottle and Pappenheimer 1941), which suggests either two components, or a substance differing in properties according to the method of purification (Stock and Verney 1952). Culture filtrates of *Str. pyogenes* also contain thermolabile (55° C. for 30 min.) hæmolysins and leucocidins which, like the erythrogenic toxin, are toxic only in large doses. The hæmolysin kills susceptible rabbits within 24-36 hours with an associated hæmoglobinuria and characteristic evidence of intravascular hæmolysis at necropsy (McLeod and McNee 1913, Channon and McLeod 1929).

One implication which has sometimes—though without justification—been attached to the term "exotoxin" is very probably misleading. Toxins of this type have been described in words which suggest that they are of the nature of active secretions of the bacterial cells. There is little definite evidence that this is so. Though some exotoxins, as that of *Cl. welchii*, are produced in high concentration during the phase of active bacterial growth, others, such as diphtheria, tetanus and Shiga toxins, only attain a high concentration in a fluid culture when the phase of active growth has passed, and the majority of the bacteria present are dead or dying. How far autolytic processes are necessary for the liberation of toxin is uncertain. In *Cl. tetani*, large amounts of toxin appear to leave the cells during autolysis (Stone 1954). Morton and Gonzalez (1954) have shown that the toxin of a culture of diphtheria bacilli with

their results indicated a very much higher concentration of toxin in the cells, though the absolute amount of toxin in the fluid was the greater.

Most of the studies on bacterial toxins have been made with crude reagents—filtrates, autolysates or extracts of fluid cultures,—which quite certainly contain many substances other than the toxins. Moreover, it is now clear that a single species of bacterium may elaborate a number of different exotoxins and endotoxins. For instance, filtrates of *Cl. welchii* Type B may contain at least five distinct exotoxins, and two major endotoxins have been isolated from virulent typhoid bacilli.

Constitution of Toxins.—Several exotoxins have been prepared in a purified

LABORATORY METHODS FOR THE STUDY OF BACTERIA¹

The study of bacteria in the laboratory by the various procedures of isolation in pure culture, cultivation, microscopic examination, and characterization by biochemical and immunological methods necessarily begins before detailed consideration of their nature and properties can be completed. The basic laboratory procedures are summarized here in didactic form, and their rationale will become apparent later.

STERILIZATION

The determination of the character and properties of a given species of bacteria is necessarily based on their study in pure culture, *i.e.*, their separation from other microorganisms. Since bacteria and other microorganisms such as fungi are ubiquitous, all material coming in direct contact with the bacteria under study must be subject to preliminary sterilization. The sterilizing agent most commonly used is heat, dry or moist, but occasionally other methods, such as filtration of liquids through bacteria-proof filters, are desirable.

Glassware and Instruments. The usual glassware includes flasks, petri dishes, test tubes and pipettes which must, of course, be scrupulously clean. Flasks and tubes are plugged with nonabsorbent cotton which prevents entry of bacteria after sterilization, and a cotton plug is inserted in the mouth end of the pipettes. Petri dishes and pipettes may be placed in cans with covers or wrapped in paper to maintain sterility. Surgical instruments are wrapped in paper or towels, syringes separated and wrapped in paper, hypodermic needles placed in plugged test tubes, and other equipment similarly prepared.

Sterilization is effected in a hot air oven, electric or gas fired. The material to be sterilized is placed in the oven without crowding and the temperature raised to 170° to 180° C. and maintained for a period of not less than two hours. If appropriate temperature control equipment is not available, a slight browning of the cotton plugs is taken as indicative of sterilization, but this is a doubtful procedure.

In some instances sterilization by heating to dull red in a bunsen flame is exceedingly useful as in the flaming of forceps tips, the platinum or nichrome wire needles and loops used for transferring bacteria, and the lips of test tubes before and after transfer of bacterial culture.

Surgical instruments, hypodermic needles and syringes, and similar equipment may be sterilized with respect to the vegetative forms of bacteria by boiling in water or 1 per cent bicarbonate solution for 3 to 5 minutes, but this does not suffice to destroy the spores of bacteria and fungi.

Culture Media and Other Liquids. Material containing water cannot, of course, be sterilized by dry heat, but moist heat is a more effective sterilizing agent in any case.

of the difficulties in determining the mode of action of bacterial toxins is the separation of the secondary effects due to tissue breakdown from the primary effects of direct intoxication by some constituent of the bacterium. The comparatively rapid action of some exotoxins, especially when administered intravenously, suggests that we are dealing with a primary effect. If, however, the effect is delayed for a few hours, it is impossible on *a priori* grounds to distinguish a latent period due to a slow penetration of toxin into, or a slow accumulation of toxin in, primarily susceptible tissue, from a latent period during which secondary toxins are being elaborated in primarily intoxicated tissues. The difficulty will probably be resolved by precise physiological and biochemical studies on the action of pure preparations of bacterial toxins. It must be realized, however, that the conspicuous effects that have been obtained in short-period observations of animals injected with fairly large doses of toxin may have little direct bearing on the relatively slow process of intoxication that occurs in natural bacterial infections (Wright 1942).

To postulate that toxins interfere with some essential metabolic processes in the animal tissues is merely another way of saying they are toxic. They may, for example, act by poisoning enzymes, rendering substrates insusceptible to enzymes, altering the quantity or quality of the products of certain enzyme processes, or by disrupting structures or surfaces upon which a balanced interrelation of metabolites depends. Peters and Cunningham (1941) could find no change in heart muscle dehydrogenase systems treated with diphtheria toxin. The toxin is reported to affect carbohydrate metabolism in rabbits by over-secretion of adrenaline; and in liver tissue of intoxicated rabbits the storage of glycogen and synthesis of carbohydrate is diminished (see Cross and Holmes 1937).

Another approach to the problem was made by Pappenheimer. Starting from the observation that in artificial culture the concentration of iron for optimal toxin and porphyrin formation is low, and that with more iron the respiratory enzyme cytochrome *b* was formed instead (Pappenheimer and Hendee 1947, 1949), he postulated that the toxin was the protein part of cytochrome *b* and as such might interfere with oxidase systems in mammalian cells that depend on iron enzymes. *In vitro* tests of this hypothesis proved inconclusive. But in the *Cecropia* silk worm, which is susceptible to the toxin in the larval and imago stage, metamorphosis to the pupal stage is accompanied by a 70-fold increase in resistance. Both larva and imago have high succinoxidase activity, which is dependent on cytochrome enzymes, but in the pupa this is apparently confined to the intersegmental muscles; and only these muscles are paralysed in pupae given toxin. Moreover, development of the pupa into imago is inhibited by small doses of toxin (Pappenheimer and Williams 1952). In the silkworm, at least, it appears that diphtheria toxin acts by blocking the synthesis of components of the cytochrome system. Conclusive evidence of a similar action in mammals is still lacking.

The mode of action of *Sh. dysenteriae* toxin is not known; but Penner and Klein (1952) record experiments indicating a direct action on the brain. They crossed the circulation of pairs of dogs, so that the systemic circulation of one supplied the cerebral circulation of the other, and *vice versa*. The absorption of toxin into the systemic circulation of one dog produced no intoxication in that animal; signs of general intoxication, on the other hand, appeared in the other animal, whose brain alone had been exposed to the toxin-containing blood of the first.

In order to explain the extraordinary potency of exotoxins in terms of the small number of molecules required to kill, it is suggested that they may act by preventing enzyme synthesis (see Pappenheimer 1948). One exotoxin, however,—the α -toxin of *Cl. welchii*—is almost certainly enzymic. Filtrates of *Cl. welchii* cultures, for example, will in large doses inhibit the aerobic oxidation of succinate by guinea-pig tissue (Wooldrige and Higginbottom 1938) and have varied actions in the whole animal, ranging from direct action

Intermittent Sterilization. As indicated above, boiling water does not provide a high enough temperature to bring about complete sterilization. Certain kinds of liquid culture media, however, are affected unfavorably by moist heat at higher temperatures, and these may be sterilized by intermittent sterilization. This is based on the assumption that the vegetative cells of microorganisms are destroyed at 100°C in the presence of water, and that the surviving spores will germinate and these vegetative cells will be destroyed in turn by exposure to 100°C . In practice the material to be so sterilized is exposed to free flowing steam in an Arnold sterilizer for 30 minutes, removed and incubated until the next day and the steaming repeated, and a third incubation and steaming is included as a safety factor so to speak. The method is not too successful in that spores not infrequently show a delayed germination, and spores of obligate anaerobic bacteria may not germinate. Sterilization by the intermittent method is, however, seldom required.

Autoclave Sterilization. The most efficient method of sterilization is that effected by steam at temperatures above 100°C . which may be produced when the steam is under pressure. The devices employed in the use of steam under pressure include the common pressure cooker, autoclaves of various designs and dressing sterilizers, which are autoclaves

too tightly in the autoclave. The temperature is raised to 120°C . and maintained for a period of time depending on the material to be sterilized. As short a time as 15 minutes

Sterilization by Filtration. It is often desirable to sterilize solutions such as bacterial cultures in liquid media, solutions of substances relatively unstable to heat such as certain sugars and the like, without subjecting them to heat at sterilizing temperatures. These may be sterilized by filtration through filters of such fine porosity that bacteria are held back. The method of sterilization by filtration is particularly useful in obtaining soluble bacterial products such as toxins.

Several kinds of bacteria proof filters are available. The Berkefeld filters are made of

is made in graded porosities, L1, L2, L3, etc., and of these the L3 is roughly equivalent to the Berkefeld N. The Seitz or Seitz-Werke filter is made of metal and the filtering element is an asbestos pad which is the equivalent of the Berkefeld N filter. Sintered glass filters are available in a variety of porosities which in the pyrex filters are designated C (coarse), M (medium), F (fine) and UF (ultrafine). The UF filter is bacteria proof while the others are not.

Filtration is accomplished by a pressure differential which may be obtained by positive pressure on the liquid to be filtered, or negative pressure on the filtrate, and usually a vacuum filter is used. The vacuum filter is used

PREPARATION OF CULTURE MEDIA

The nutritive requirements of bacteria vary greatly, some will grow readily in the so-called synthetic media containing inorganic salts, including an am-

It is possible that adrenal stimulation and damage may play some part in the production of these effects (see Evans and Zeckwer 1927, Olitzki, Avinery and Koch 1942). In *Sh. dysenteriae* Olitzki and his colleagues (Olitzki, Leibowitz and Berman 1937, Olitzki and Avinery 1937) distinguish a toxic fraction and separate fractions producing leucopænia, glycaemia and hypothermia respectively. It is not certain how far their fractions were made up of complete endotoxin, and of breakdown products therefrom.

Other Active Constituents or Products of Bacteria.

We have already noted certain specific or non-specific biological characteristics of toxins; and many others, like the hæmolysins and leucocidins of *Staph. aureus*, could be instanced. In this section we are concerned with bacterial products that are not particularly toxic in themselves, but act upon animal tissues and fluids, or upon substrates known to occur in animal tissues, in such a way as to suggest that they may influence the course of a bacterial infection. As with the toxins, the proof of their auxiliary powers in infection depends ultimately on demonstrating their activity in the natural infection, either directly, or indirectly, by the protective action of antibodies and other specific inhibitors of the substance in question. In this group of bacterial substances particularly, it is to be emphasized that the mere association of a biochemical property and pathogenicity, either in a bacterial species or in the more virulent strains of a pathogenic species, is not by itself evidence that the property is concerned in infection by the species. As we have seen in the chapter on variation, latent activities of bacteria can be made manifest by the provision of suitable substrates, and though a virulent bacterium may exhibit an activity because a suitable substrate is present in the tissues of its host, it does not necessarily follow that the virulence depends on the capacity to attack the particular substrate; the capacity may in this respect be purely accidental.

Coagulase.—Among the staphylococci, the more pathogenic *Staph. aureus* produces a coagulase that accelerates the clotting of human and rabbit plasma (Much 1908, Gross 1931a, b, Gengou 1933, Chapman *et al.* 1934). Since the formation of fibrin clots is a striking feature of *Staph. aureus* lesions in man and animals, it is natural to relate the two features. Nevertheless, Menkin and Walston (1935) could find no evidence that staphylocoagulase was concerned in the production of the staphylococcal lesions.

Susceptibility of plasma to coagulase varies with the species (see also Gerheim and Ferguson 1949). Guinea-pig plasma, for example, is usually not affected. Smith and Hale (1944) found that susceptibility depended on an activator in plasma; and that activator from susceptible human or rabbit sera made guinea-pig plasma susceptible. Although its identity is not fully established, the activator resembles prothrombin in many respects (see Tager and Hales 1948a, Duthie and Lorenz 1952).

The auxiliary rôle of coagulase is based on the association of coagulase α -toxin production in clinically infecting strains of *Staph. aureus*, (see Schwabacher *et al.* 1945); the association of species insusceptibility to staphylococcal infection, as in fowls, rats and mice, with insusceptibility to coagulase (Hale and Smith 1945); the fact that coagulase-production confers resistance to phagocytosis on strains of *Staph. aureus* tested in the presence of a coagulable plasma (Hale and Smith 1945); and the increase in virulence of coagulase-producing *Staph. aureus* for mice, when injected with a coagulable plasma from another species (Smith *et al.* 1947). Coagulase is antigenic (Tager and Hales 1948b), and antibody to it occurs in the serum of patients with chronic staphylococcal infections (Duthie and Lorenz 1952). Finally, according to Duthie (personal communication), there are two coagulase factors, one bound to the cell, the other free. The bound factor is liberated on autolysis of the cell, acts directly on a susceptible fibrinogen, and is neutralized by

monium salt, together with a simple organic compound such as glucose or asparagin as a source of carbon and energy. In general, bacteriological media have been developed on a trial and error basis about a basic nutrient medium containing peptone and the water-soluble material, largely extractives, of muscle tissue. The source of the latter may be commercial preparations of meat extract but a somewhat better medium is obtained if these substances are extracted from fresh meat, beef or veal for the most part.

The basal nutrient solution may be modified in a variety of ways. Thus, it may be solidified by the addition of gelatin or agar, or enriched with serum, ascitic fluid, defibrinated blood and the like to support the growth of the more fastidious bacteria. Various sugars may be added, together with an acid-base indicator, for the determination of the fermentative properties of bacteria; nitrate or tryptophane may be added to test for ability to reduce nitrate to nitrite, form indol from tryptophane, etc. Or culture media may be prepared which are differential and accentuate physiological differences, and specific inhibitory agents may be added to give selective media which allow the growth of some kinds of bacteria and suppress that of others. These various characteristics may be combined, of course, as in the case of an enriched medium which is both selective and inhibitory. In consequence, there is a great variety of bacteriological culture media, but they are in large part interrelated modifications of a basal nutrient solution. The constituents and method of preparation of a few of the commonly used culture media may be reviewed here.

Basal Media

Meat Extract Broth and Agar. The medium usually has the following composition:

meat extract	3 gm.
peptone	5 gm.
(NaCl	5 gm.)
agar	15 gm.)
distilled water	1000 ml.

It is necessary to include the sodium chloride if the medium is to be used for serological work or enriched with blood, and the agar is omitted if a liquid medium is desired. The ingredients are dissolved in water. Agar has the property of not dissolving or of its gels the temperature heat it in the y acid and the

reaction is adjusted to pH 7 by the addition of alkali.

Meat Infusion Broth and Agar. The infusion media differ from the extract media in that the extractives are obtained by infusion of fresh meat, but otherwise the composition is the same, viz.

extract of 400 to 600 gm. fresh lean beef or veal	
peptone	5 gm.
(NaCl	5 gm.)
agar	15 gm.)
distilled water to	1000 ml

The meat is ground in a meat chopper, suspended in 1 liter of distilled water, and infused overnight in the refrigerator. The following morning the fat is skimmed off with absorbent cotton and the infusion squeezed through muslin and made up to 1000 ml. The other ingredients are added, the reaction adjusted to pH 7, the solution heated to 100° C. for about 20 minutes, regardless of whether agar is used, filtered through coarse paper and made up to 1000 ml. The heating is for the purpose of coagulating the tissue proteins dissolved during infusion so that they can be removed by filtration.

been found in members of the *Bacterium*, *Pasteurella*, *Rickettsia*, *Bacillus*, *Brucella*, *Vibrio*, *Haemophilus* or *Neisseria* groups (see also Ungar and Bacharach 1942).

The identity of certain mammalian and bacterial diffusing factors with the enzyme hyaluronidase was first suggested by Chain and Duthie (1940). The parallelism is not complete (Hobby *et al.* 1941, Meyer *et al.* 1941), but it is clear that most bacterial spreading factors owe their activity to one or more enzymes catalysing different stages in the breakdown of polymers of hyaluronic acid (McClellan 1941, McClellan and Hale 1941, Rogers 1945, 1946, 1948, Humphrey 1946). The intercellular ground substance of mesodermal tissue contains hyaluronic acid in a viscous polymerized form, and it appears that the enzyme hydrolyses the viscous polymer and thus permits the ready diffusion of fluid through the intercellular spaces.

It is evident that the addition of hyaluronidase to the inoculum enhances the virulence of the contained organisms in certain experimental infections. In others, it has no effect, or decreases their virulence. As we have already noted, a decrease in virulence is explicable on the grounds that the inoculum is dispersed. Its efficacy also depends on the pressure engendered at the site of inoculation when the injection is made (Hechter 1947). Given, for example, in the allantoic sac of the chick embryo, hyaluronidase does not affect influenza viral infections (see Fastier 1951, Henneberg and Ortmann 1951). In natural infections, therefore, we might expect a bacterial hyaluronidase to promote the spread of infection in oedematous lesions where the exudate is under increased pressure, provided that the spread of the invader took place into susceptible and not into resistant tissue. McClellan and his colleagues (1943) detected large amounts of hyaluronidase in well-established local lesions by *Cl. welchii*, *Cl. septicum* and certain strains of *Cl. oedematiens*, and it is reasonable to postulate that in such circumstances the spread of the hyaluronidase-producing organisms would be facilitated by the enzyme. But it may be argued that, in the very early stages of a natural infection when the growing bacterium is present in small numbers, hyaluronidase, by promoting a rapid dispersal of the bacteria through healthy tissues, would expose invading organisms more thoroughly to the lethal action of the tissues (see, *e.g.*, Dalgaard-Mikkelsen *et al.* 1950).

The production of hyaluronidase, like that of coagulase and fibrinolysin, is associated with virulent species of bacteria, and to some extent with the virulent strains within a species. The association between invasiveness and hyaluronidase production is by no means complete. Thus some highly invasive strains of *Cl. welchii* produce none (Evans 1943b); and the same is true of certain types of *Str. pyogenes* obtained from severe human infections (Crowley 1944) and of streptococci that prove pathogenic for chick embryos and laboratory animals (Russell and Sherwood 1949, Sherwood *et al.* 1952). Some Group A streptococci, which depend in part upon the presence of a mucoid capsule containing hyaluronic acid, also secrete hyaluronidase (Pike 1948). That they may thereby decrease their own virulence is evident from the protective and curative effect of hyaluronidase in experimental infection by streptococci possessing hyaluronate capsules (Kass and Seastone 1944, Rothbard 1948). Bacteria like *Brucella melitensis* and *tularensis* and *Pasteurella pestis* which are highly invasive in the accepted sense of the word, produce no hyaluronidase.

and the tubercle bacillus (Bergqvist and Packalen 1948)—an effect attributed to hyaluronidase. Humphrey (1944) found no relation between *in vitro* hyaluronidase production by pneumococci and the severity of the human infection they caused, though in 20 strains Grumbach and Kradholfer (1945) related high productivity with rate of spread of the lung lesions, as measured by X-rays. Thompson (1948) found the anti-hyaluronidase response in pneumonia to be directly related to the severity of the disease. This suggests considerable *in vivo* production; but the high productivity may have been merely the result, and not the cause, of extensive bacterial proliferation.

From the foregoing evidence we see that the auxiliary pathogenic rôle of hyaluronidase in natural infection is largely conjectural. A more convincing proof might be obtained

Media for Biochemical Tests

Sugar Broths. The sugar broths are meat extract or meat infusion broth to which the required carbohydrate has been added to a concentration of 1 per cent. Unless the carbohydrate is stable to autoclave sterilization, it must be sterilized separately by filtration in concentrated solution and added aseptically to the sterile broth. It is customary to add an acid base indicator dye, bromthymol blue or bromcresol purple, and the medium may be dispensed in culture tubes containing an inverted vial that fills during sterilization and serves to collect gas evolved in the fermentation of the sugar.

Nitrate Broth. To test for ability to reduce nitrate, bacteria are cultured in nitrate broth, infusion or extract broth containing 0.1 per cent KNO_3 . The culture is tested for the presence of nitrite with sulfanilic acid and α -naphthylamine reagents.

ml
par
by filtration through absorbent cotton.

To test for nitrite add 2 ml. of each of the two reagents to 3 to 5 ml. of culture, the development of a rose color, the nitroso reaction, indicates the presence of nitrite.

Tryptophane Broth. The test for the production of indol from tryptophane can often be
tryptone contains adequate amounts of the amino acid

The presence of indol is tested for after 2 to 4 days' incubation of the culture by layering a small amount of Ehrlich's reagent on the surface of the culture, the development of a red color at the interface indicates the presence of indol. If a color does not appear within 1 minute, add a small amount, equal to that of the Ehrlich reagent, of saturated aqueous solution of potassium persulfate.

Ehrlich's reagent consists of 4 gm. of *p*-dimethylaminobenzaldehyde dissolved in a mixture of 380 ml. of ethyl alcohol and 80 ml. of concentrated hydrochloric acid.

Lead Acetate Agar. This medium is meat extract or meat infusion agar containing 0.05 per cent basic lead acetate and dispensed in culture tubes without slanting. It is usually prepared by mixing equal amounts of sterile double strength basal medium, i.e., containing double amounts of the ingredients, and sterile 0.1 per cent aqueous solution of basic lead acetate.

The medium is inoculated by stab and the production of hydrogen sulfide from the sulfur-containing amino acids of the peptone is indicated as a blackening or browning of the medium.

Meat Extract and Meat Infusion Gelatin. These media are the basal media solidified

by chilling. Gelatin liquefaction sometimes occurs slowly and cultures should be retained for not less than two weeks unless positive earlier.

Milk. Milk is an adequate culture medium for many bacteria without modification other than the addition of an indicator, bromcresol purple or litmus in an amount of 5 ml. of a 0.25 per cent alcoholic solution per liter. Fresh skim milk may be used, but skim milk powder is usually more convenient. One liter of medium is made from 150 gm. of milk powder, first rubbed up in a mortar and then diluted to volume. Medium prepared from powdered milk may be autoclaved, but that from fresh milk is best sterilized by the intermittent method.

Because of its protein and carbohydrate content milk cultures undergo a variety of biochemical changes, viz.:

(1) The development of an alkaline reaction, usually after 3 to 4 days' incubation.

act as a powerful stimulus. In some cases the vigorous response evoked is injurious to the host, so that a bacterial product which possesses little or no toxicity for a normal animal may be highly toxic for an animal which has become sensitized by infection. The well-known tuberculin reaction in the guinea-pig is a case in point.

Some Illustrative Examples.

We have described above the various bacterial factors which, so far as we know at the moment, are certainly, probably, or possibly concerned in the pathogenesis of infective diseases.

A few illustrative examples may serve to emphasize the more important points.

Botulism may be placed at one end of the scale, as an example of a pure toxæmia. It is not a true infection, but is closely analogous to the effects that may follow the consumption of such vegetable poisons as those produced by certain fungi or plants. There is no certain evidence that *Cl. botulinum* ever invades the tissues, or multiplies in them. Man is affected by eating food in which the organism has grown and produced its toxin.

Tetanus is one step removed, in that the bacillus must gain access to the tissues and multiply in them in order to produce its toxic effects; but its invasive powers are very slight. It usually gains access to the body as the result of some mechanical injury, and the local multiplication of the organism is often assisted by gross injury to the tissues, by the injurious effects of some associated infection, or by the presence of some chemical agent which damages the local defensive tissues.

Diphtheria takes us a little further along the scale. The bacillus is capable of implanting itself in the faucial region, and of spreading from host to host, by ordinary droplet infection or in similar ways. It has relatively slight but quite definite invasive powers. It causes a characteristic local lesion, and may occasionally invade other tissues and organs. Its lethal effect, however, depends almost entirely on its activity as a toxin producer.

The hæmolytic streptococcus combines the activities of a typically toxigenic organism with those of the highly invasive group of bacteria. It produces a relatively heat-stable toxin, with a characteristic action on the skin, which is the cause of the typical toxic rash in scarlet fever; but it also invades the tissues freely. Indeed, highly virulent strains of the organism are among the most rapid and vigorous tissue-invaders with which we are acquainted in human pathology. In relation to this tissue invasion it is probable that the leucocidin, and perhaps the hæmolysin, fibrinolysin and hyaluronidase produced by pathogenic streptococci play a significant part.

As we move along the scale we meet a variety of organisms whose pathogenicity seems to depend entirely on their power of spread and multiplication in the tissues, and whose more important effects seem to be localized to the areas in which such multiplication occurs. These differ among themselves in selective localization, and in the tissue reactions to which they give rise. Thus, staphylococci most commonly cause localized suppurative lesions, with a varying degree of lymphatic spread, which may sometimes be rapid and extensive. More rarely they give rise to a generalized infection of the pyæmic type, in which the cocci are carried from the original focus of infection in detached fragments of an infected thrombus. Here again, leucocidin, coagulase, and perhaps hæmolysin, fibrinolysin and hyaluronidase, may play a part in determining the type of lesion in any particular case.

Finally, there are organisms, such as the tubercle bacillus, the leprosy bacillus

Laboratory Methods for the Study of Bacteria

- (2) The development of an alkaline reaction with precipitation of the casein as a rennet curd, with or without reduction of the indicator.
- (3) The development of alkalinity and rennet curd precipitation, followed by peptonization or digestion of the curd, resulting in a clearing and brownish discoloration; the indicator is usually reduced by the time digestion is apparent.
- (4) Acid formation, usually in 24 hours, with or without reduction of the indicator.
- (5) Acid formation and precipitation of the casein, usually with reduction of the indicator.

Enriched Media. Basal infusion media may be made richer by the use of special peptones, such as neopeptone and proteose peptone, and the addition of small amounts of glucose and phosphate buffer. In addition, fluids such as serum, ascitic fluid or defibrinated blood may be added.

Blood Agar The most common and most useful enriched medium is blood agar—veal or beef infusion base to which defibrinated whole blood is added. The blood is usually taken from the rabbit, sheep or horse under sterile conditions and defibrinated as it is drawn by shaking with glass beads. The sterile infusion agar base is liquefied by heating, cooled to about -45°C , the sterile blood added to 10 per cent concentration, and the medium dispensed before it solidifies, usually in petri dishes or as slants in culture tubes. The entire operation is carried out under sterile conditions and the medium incubated for 24 hours to detect contamination, and then stored in the refrigerator. This medium is rich enough to support the growth of almost all the fastidious pathogenic bacteria and has the advantage that hemolysis is shown directly in the cultures.

Cystine Blood Agar This is simply blood agar medium further enriched by the addition of 0.01 per cent cystine and 1 per cent glucose to the basal medium prior to the addition of blood as above. It is useful primarily in the cultivation of *Pasteurella tularensis*.

Chocolate Agar. This medium is heated blood agar and is particularly useful for the cultivation of the gonococcus and meningococcus. Formulae vary somewhat, some workers preferring a beef heart infusion (see below) instead of muscle tissue infusion and proteose peptone instead of peptone. The basal infusion medium is enriched by the addition of defibrinated blood as in the preparation of blood agar, but after the addition of the blood, it is heated slowly in a water bath until the medium has a chocolate brown color, if the heating is excessive the blood coagulates and the finished medium will contain clumps of cooked blood, so that the temperature should not rise above 75°C . at the most.

Other Infusions. The use of infusions of tissues other than beef or veal muscle is sometimes desirable for the cultivation of certain bacteria. Beef liver infusion is prepared in the same manner as that described for the other infusions and, for culture of Brucella, for which liver infusion medium is particularly useful, the basal medium is enriched by the addition of 1 per cent egg albumin. Beef heart infusion is also prepared in the same manner as beef muscle infusion and the basal medium completed by the addition of a peptone, sodium chloride, etc.

Löffler's Medium. This medium is used primarily for culture of the diphtheria bacillus and consists of 3 parts of sterile beef serum and 1 part of meat infusion basal medium containing 1 per cent glucose. The serum is added to the sterile base, mixed, dispensed in culture tubes, slanted and sterilized by the intermittent method. Sterilization may be carried out on three successive days in the autoclave at 15 pounds steam pressure without letting the air out, or it may be held at 15 pounds for 15 minutes and the air allowed to escape slowly while maintaining pressure and, when all the air has escaped, holding for an additional 15 minutes, and after sterilization allowing the pressure to fall very slowly. The medium is solid because of coagulation of the serum and sterilization must be carried out carefully to avoid the formation of bubbles.

Blood Culture Medium (Kracker). This is a highly enriched medium containing beef heart infusion and brain suspension and is used primarily for blood culture of bacteria in infections accompanied by bacteremia. Its composition is:

been most extensively studied in Gram-negative bacteria, where they appear to confer on the cell the main serological properties of the virulent S forms.

(6) There are other substances in bacterial cells which are not in themselves toxic, but whose nature—the capacity to induce or inhibit the coagulation of plasma or lymph, to dissolve a fibrin clot, or to increase the local intercellular permeability of tissues—suggests that they may influence the course of the infective process; and it is possible that other enzymes concerned in bacterial metabolism may have a like influence in infection by alteration of the metabolism of the tissues.

(7) The pathogenic rôle of these auxiliary factors, and even of endotoxins that have no specific effect on the host's tissues, is often difficult to establish. In doing so, it is necessary in the first place to define the stage and circumstances of the natural infection in which the presumed auxiliary factor is effective and, if possible, to demonstrate the effect in these circumstances. The association of the factor with virulent strains of an organism, and the antibody response to the factor in the infected host, are of limited value as evidence. When the factor is antigenic, the most convincing evidence of its participation is a curative or protective effect of antibody specific for the factor.

(8) As the result of infection the tissues of the host may become hypersensitive to the infecting bacteria or to their products. Hypersensitivity reactions may be responsible for some of the characteristic phenomena of infective disease.

heart infusion	750 ml
brain suspension	250 ml
sodium citrate	1 gm
dextrose	10 gm.
peptone	10 gm.
dibasic sodium phosphate	2 gm
sodium chloride	4 gm

The heart infusion is prepared in the same manner as muscle tissue infusion described earlier. The brain suspension is prepared by maceration of 500 gm. of fresh brain in water, straining through a metal strainer and heating slowly to boiling with constant stirring. The heating coagulates the brain tissue and leaves it in a state of fine suspension, it must not be filtered. The other ingredients are added to the mixture of heart infusion and brain suspension, the pH is adjusted to 7.4, the mixture is dispensed in 50 ml. amounts in 100 ml. flasks (to leave room for an inoculum of 10 to 20 ml. of patient's blood) and sterilized by autoclaving. Cultures in this medium are essentially enrichment cultures and should be subcultured on appropriate agar media such as blood agar for streptococci and staphylococci, liver infusion agar for *Brucella*, etc.

Dorset's Egg Medium. This medium is used for the cultivation of the tubercle bacillus and consists of 4 fresh eggs and 25 ml. of 0.85 per cent sodium chloride solution. The eggs are scrubbed with a brush in soap and water, rinsed, dried, put into a wire basket and dipped into 95 per cent alcohol, drained and the remaining alcohol ignited. They are then broken using aseptic technique and the whites and yolks placed in a sterile container. Twenty five ml. of sterile salt solution is added, the whole mixed well with a sterile egg beater, dispensed in culture tubes and slanted, and sterilized by the intermittent method described for Löffler's medium.

Differential and Selective Media. The various differential and selective media have been designed to facilitate the isolation of one kind of bacteria in the presence of many other kinds, by accentuating physiological differences and/or inhibiting the growth of the

fermenting bacteria are yellow while those of the non fermenters are blue. Of the selective agents bacteriostatic dyes are often used, and others include bile, tellurite, etc.

Endo's Medium. This medium consists of meat extract agar to which has been added lactose and Schiff's reagent, basic fuchsin decolorized with sulfite. When the lactose is fermented aldehyde intermediates restore the color to the fuchsin and colonies of lactose fermenting bacteria are red while those of the non lactose fermenters are white. The composition of the medium is

hot melted extract agar	1000 ml.
sodium carbonate, 10% aqueous	10 ml
lactose	10 gm
sodium bisulfite, 10% aqueous	10 ml.
basic fuchsin, 3% alcoholic	10 ml.

The pH of the medium is raised by the carbonate and should be 7.6 to 8.0.

Eosin-Methylene Blue Agar. This medium is sterile meat extract agar to which is added 5 ml. of a 10 per cent solution of lactose, 2 ml. of 2 per cent aqueous eosin and 2 ml. of 0.5 per cent aqueous methylene blue. These solutions are added aseptically to the melted and cooled medium and the mixture is dispensed in sterile petri dishes.

Desoxycholate Citrate Medium. This medium is differential in that it contains lactose and neutral red as an indicator, and selective in that it contains bile salt, and is one of the

been most extensively studied in Gram-negative bacteria, where they appear to confer on the cell the main serological properties of the virulent S forms.

(6) There are other substances in bacterial cells which are not in themselves toxic, but whose nature—the capacity to induce or inhibit the coagulation of plasma or lymph, to dissolve a fibrin clot, or to increase the local intercellular permeability of tissues—suggests that they may influence the course of the infective process; and it is possible that other enzymes concerned in bacterial metabolism may have a like influence in infection by alteration of the metabolism of the tissues.

(7) The pathogenic rôle of these auxiliary factors, and even of endotoxins that have no specific effect on the host's tissues, is often difficult to establish. In doing so, it is necessary in the first place to define the stage and circumstances of the natural infection in which the presumed auxiliary factor is effective and, if possible, to demonstrate the effect in these circumstances. The association of the factor with virulent strains of an organism, and the antibody response to the factor in the infected host, are of limited value as evidence. When the factor is antigenic, the most convincing evidence of its participation is a curative or protective effect of antibody specific for the factor.

Laboratory Methods for the Study of Bacteria

most satisfactory and widely used media for the isolation of *Salmonella* and dysentery bacilli. It contains

meat infusion	1000 ml.
peptone	10 gm.
agar	20 gm.
lactose	10 gm.
sodium citrate	20.6 gm.
sodium desoxycholate	5 gm.
lead chloride, 0.35% aqueous	1 ml.
ferric ammonium citrate	2 gm.
neutral red, 1% aqueous	2 ml.

The complete medium is not stable on storage. The peptone and meat infusion are mixed, the pH adjusted to 7.5. The solution is boiled for 3 minutes, lost water added, and filtered through paper. The agar is added to the hot solution together with 5 ml. of N NaOH and it is allowed to stand for 15 minutes, then steamed at 100° C. for 20 minutes. Then the lactose, citrate, desoxycholate and lead chloride are added. This may be stored and remixed for use. Just before use, the agar is heated to 100° C., the ferric ammonium citrate added and the pH adjusted to 7.4 using phenol red as an indicator, and finally the neutral red is added and the medium dispensed in plates. Note that it is not autoclaved.

Bismuth Sulfite Medium (Hajna). This medium is used primarily for the isolation of the typhoid bacillus from fecal specimens and is highly specific for that organism. As originally developed it was difficult to prepare consistently but Hajna's modification is highly satisfactory. It consists of a meat extract agar base containing 0.5 per cent glucose, the bismuth sulfite mixture and brilliant green. The bismuth sulfite mixture is prepared as follows

- (1) Dissolve 80 gm. of anhydrous bismuth sulfite in 400 ml. of hot water with stirring.
- (2) Make a paste of 24 gm. of bismuth citrate in 40 ml. of water, add 12 ml. of concentrated ammonia and stir until a sol is formed. Dilute to 200 ml. with distilled water and mix to give a solution.
- (3) Mix (1) and (2) and add 42 gm. of anhydrous diarsenic sodium phosphate and mix until dissolved.
- (4) Dissolve 4 gm. of ferrous sulfate in 50 ml. of distilled water containing 2 drops of concentrated hydrochloric acid, and add 40 ml. of this solution to mixture (3). Mix and boil gently for about 2 minutes until slate gray in color. This is the bismuth sulfite mixture and it is stable for about 2 months.

For use add 70 ml. of the bismuth sulfite mixture and 4 ml. of a 1 per cent aqueous solution of brilliant green to each 1000 ml. of the hot melted agar base and autoclave for not more than 10 minutes, and dispense in petri dishes. The complete medium may be kept for perhaps 2 weeks in the refrigerator without autoclaving, and should be autoclaved just prior to dispensing.

Tetrathionate Enrichment Broth. Nutritive enrichment broths are used for preliminary culture of specimens followed by subculture on selective differential media. Tetrathionate broth and selenite F broth (see below) are very useful in the isolation of *Salmonella* from fecal specimens. The active agents in tetrathionate broth are bile salts, brilliant green and tetrathionate, the last formed by oxidation of thiosulfate with iodine just prior to inoculation. Its composition is as follows:

proteose peptone	5 gm.
bile salts (Bacto)	1 gm.
distilled water	1000 ml.
calcium carbonate	10 gm.
sodium thiosulfate	30 gm.
brilliant green, 1% aqueous	11 ml.
iodine, 25% aqueous	25 ml.
potassium iodide	per 100 ml.
water to	25 gm.
	20 gm.
	100 ml.

The peptone and bile salts are dissolved in water and calcium carbonate added, and autoclaved. The sodium thiosulfate and brilliant green are added to the sterilized medium and it is dispensed in tubes or small flasks. Just prior to inoculation add the iodine solution in the proportion of 2.5 ml per 100 ml.

Selenite F Broth. This medium contains selenite as an inhibitory agent and its composition is:

sodium hydrogen selenite	4 gm.
peptone	5 gm.
lactose	4 gm.
sodium phosphates (anhydrous)	10 gm.
distilled water	1000 ml.

It is necessary to determine the proportions of acid and basic phosphates which will give a final reaction of pH 7.0 to 7.1 with the peptone and the lot or brand of selenite used. The ingredients are dissolved in warm water, and then brought to a boil and dispensed. The medium is not autoclaved.

ml. of infusion base. It is used for culture of diphtheria bacilli.

Petragnani's Medium This is a medium used for culture of tubercle bacilli and contains malachite green to inhibit the growth of gram positive bacteria and molds. Its composition is:

milk	900 ml.
potato flour	36 gm.
peptone	6 gm.
pieces of potato, size of an egg	6
eggs	24
egg yolks	6
glycerin	72 ml.
malachite green, 2% aqueous	60 ml

The potatoes are cut into thin slices, the milk, potato flour and peptone added, and the whole cooked in a double boiler for 2 hours with stirring. The eggs and egg yolks are broken together, the glycerin and malachite green added, and the mixture shaken well. The milk potato mixture is cooled to 50° C, the egg glycerin-dye mixture added and mixed well, and the whole is filtered through gauze, dispensed into tubes, slanted and sterilized by the intermittent method described for Löffler's medium.

MICROSCOPIC EXAMINATION OF BACTERIA

The direct observation of bacteria is an essential part of their study. Characteristics such as the shape and grouping of the cells, the presence or absence of structures such as capsules, flagella and spores, the reaction to differential stains, and the like are of considerable differential significance.

Motility. Some bacteria are motile by virtue of organs of locomotion, flagella, to the cell. Motility can be observed if the living bacteria are mounted in a drop of liquid on a coverslip inverted over a hollow ground or depression slide. Motility is to be differentiated from brownian movement, the latter is a dancing irregular movement, while motile bacteria move across and in and out of the microscopic field, and the movement may be surprisingly rapid.

were dead within 30 minutes. On the palmar surface of the clean hand *Bact. coli*, *Salm. typhi* and *Salm. enteritidis* could not be detected after 10 minutes, though in certain regions, under the nail-tip and along the lateral margins of the finger nails, the bacteria persisted longer. There was a rapid initial reduction of *Staph. aureus* on the palmar surface of the hand, but small numbers persisted for long periods. The skin of dirty hands had less self-sterilizing power, the reduction of *Salm. enteritidis* being 5 per cent. in 20 minutes; after washing the reduction was 100 per cent. in 20 minutes. Fifteen minutes after the death of the skin, most of the bactericidal action for *Bact. coli* had disappeared.

It should be noted that not only may bacteria be killed, but viruses may be inactivated on skin. Influenza virus, for example, in one series of experiments, could not be detected 10 minutes after application to the human skin (U.S. Navy Medical Bulletin 1943); though in another series (Parker and MacNeal 1944) suspensions of virus in the allantoic fluid of the chick survived 45 to 50 minutes on the skin of the hand.

Arnold and his colleagues attach considerable importance to the effect on bacteria of the pH of the skin, which is usually acid (5.8-5.2, see Schade and Marchionini 1928). Marchionini and others (1938), using a skin electrode, found the greater part of the skin surface was acid, the pH in some spots being as low as 5 or even 3. There were alkaline areas in the axillæ and groins, between the toes and on parts of the foot, which they regarded as gaps in the "acid coat" that constitutes a defence against infection of the skin. The flora of skin was scantier in the acid areas and, in these, applied *Chromobacterium prodigiosum* disappeared more rapidly than in the alkaline areas. After induced sweating the skin increased in acidity, and was more bactericidal. Bergeim and Cornbleet (1943) attribute the acidity to the lactic acid excreted in sweat, and to the volatile acids formed from it by bacterial action. The former is active in regions where the pH of the skin is 5.3 or less; at a higher pH, it dissociates and loses much of its bactericidal power. The latter are active at a pH of 5.3 to 6.2, and will consequently be effective in the more alkaline areas of the skin.

The readiness with which *Str. pyogenes* is killed on the skin has been partly elucidated by Burtenshaw (1938, 1942) (see also Williams *et al.* 1943) who extracted, from normal living or dead skin, substances resembling long-chain fatty acids and soaps that were markedly bactericidal for *Str. pyogenes*, but not for *Staph. aureus*.

Hellat (1948) largely discounts Arnold's hypotheses. He found rapid death on the skin of *Pr. vulgaris* and *Bact. coli*; death within a day of *Ps. pyocyanea* and *Chr. prodigiosum* and within a few days of hemolytic streptococci; and prolonged survival of *Staph. aureus* and enterococci. For most of his bacteria, desiccation was a sufficient explanation. The survival of *Staph. aureus*, and its habitual presence on normal skins (see Chapter 67), he suggests are due to its capacity for multiplying in water-poor substrates (see also Rebell *et al.* 1950). Ricketts and his colleagues (1951) confirmed the rôle of desiccation in the death of *Ps. pyocyanea* and *Bact. coli*, which survived for long periods on moist skin. They identified oleic acid as a major constituent of streptococcicidal fatty acid in the skin. Together with desiccation, this acid likewise appeared to play a large part in killing *Staph. aureus*.

Fleming (1922, 1929, 1932) recorded the presence in tears, in nasal secretion, and in many tissues including the skin, of a relatively thermolabile substance which, in high dilution, causes the lysis of certain non-pathogenic bacteria, and in particular of an organism to which he gave the name of *Micrococcus lysodeikticus*. This substance, lysozyme, is an enzyme (Meyer *et al.* 1936, Abraham 1939) which appears to initiate lysis by splitting certain polysaccharide components of susceptible bacteria (Epstein and Chain 1940). It is active against some strains of staphylococci, and of intestinal streptococci of human origin. In high concentration it acts, though less energetically, on other pathogenic bacteria. It is natural to inquire whether it plays any part in the self-disinfecting action of the human skin. The evidence is conflicting. According to Colebrook (1930) many of the bacteria that are rapidly removed are not susceptible to its action. *Micrococcus lysodeikticus* itself disappears less rapidly from the skin than such species as *Str. hemolyticus*,

For demonstration of motility the culture should be young, not more than 18 hours old. Bacteria from cultures on agar media must be suspended in saline, while broth cultures may be used directly. A drop of suspension or culture is placed in the center of a cover slip. The depression in the hollow ground slide is lined with petrolatum on the surface around the depression, and inverted over the cover slip. The cover slip sticks to the slide and evaporation is prevented by the seal. The preparation is turned over and examined under the oil immersion lens. Unstained bacteria are difficult to see and the diaphragm should be closed to a small aperture, it is best to focus first on the edge of the drop.

Staining. Bacteria may be stained or dyed with aniline dyes, more readily with the basic dyes.² Staining may be with a single dye, or simple stain, most commonly crystal violet, methylene blue or basic fuchsin, with mixed dyes or polychrome stains, or by differential methods based on the relative affinity of different bacteria or different structures of the bacterial cell for the stains used. The nature of the staining process has been a matter of considerable controversy, in large part as to whether it is fundamentally a physical or chemical process. It is now generally agreed that it is chemical in nature and the mechanism an ionic interchange between the basic dye and the acidic portions of the protoplasm—nucleic acids and their compounds—with the formation of insoluble dye-nucleotide compounds that do not diffuse out of the cell.

Stain Solutions. The composition of stain solutions varies considerably in the literature. The several, frequently somewhat indefinite, formulae have been interpreted by the Committee on Biological Stains and are given here in the emended form recommended by that Committee. In older formulae the dye content is often given as ml. of a saturated alcoholic solution, and the accompanying table gives the solubilities of those most commonly used, in water and in 95 per cent alcohol.

SOLUBILITIES OF COMMON BACTERIOLOGICAL STAINS²

Color Index Number	Name	Per Cent Soluble in	
		Water	95% Alcohol
655	Auramine O	0.74	4.49
681	Crystal violet (chloride)	1.68	13.87
676	Fuchsin, basic (pararosanilin hydrochloride)	0.26	5.93
657	Malachite green (oxalate)	7.60	7.52
922	Methylene blue (hydrochloride)	3.55	1.48
841	Safranin	5.45	3.41
925	Toluidine blue O	3.82	0.57

Löffler's Alkaline Methylene Blue

Solution A.

methylene blue (90% dye content) 0.3 gm.
ethyl alcohol (95%) 30 ml.

Solution B.

ddute KOH (0.01% by weight) 100 ml.

The two solutions are mixed in the above quantities.

Ziehl's Carbol-Fuchsin

Solution A

basic fuchsin (90% dye content) 0.3 gm.
ethyl alcohol (95%) 10 ml.

² See *Biological Stains*. Prepared by the Commission on the Standardization of Biological Stains, 11. J. Conn, chairman. 3rd ed. Geneva, N. Y. 1940.

upper part of the duodenum to the action of the gastric juice, with its high hydrogen-ion concentration. It has long been recognized that the gastric secretion imposes a barrier to the passage of bacteria from the mouth to the intestine, but the careful studies of Arnold and his colleagues (Arnold 1926, 1927, 1928, 1929, Arnold and Brody 1926a, b) have placed our knowledge on a more detailed basis. By fixing various segments of the gastro-intestinal tract of the dog to the skin of the abdomen they were able to withdraw samples of the contents by sterile puncture as desired, and thus to determine the nature of the normal flora in relation to the acidity or alkalinity of the intestinal contents, and also the fate of other bacteria when administered by the mouth.

Table 65 shows the relation between the hydrogen-ion concentration of the intestinal contents and the prevailing bacterial flora at different levels.

TABLE 65

Portion of Small Intestine.	pH of Contents.	Bacterial Flora.
Duodenum	5.2-6.0	Few Gram-positive cocci.
Jejunum, upper half . . .	5.5-6.5	"Gram-positive" cocci, "few Gram-positive and Gram-negative bacilli.
Jejunum, lower half . . .	6.0-7.0	Rich and varied bacterial flora.
Ileum	6.8-8.0	

When watery suspensions of *Chromobacterium prodigiosum* and *Ps. pyocyanea* are put into the empty stomach of a dog 12 to 18 hours after a meal, they fail to reach the cæcum. Introduced in an alkaline buffered watery suspension or in alkaline buffered milk they reach the cæcum in large numbers. (See also Teale 1934 and Chapter 90). Whether the bactericidal action of the duodenal contents is entirely determined by its hydrogen-ion concentration, is, perhaps, open to question (see Meyer and Löwenberg 1928).

Garrod (1937) found that gastric juice was bactericidal for a number of organisms that infect by the mouth. *Br. abortus* was most susceptible; and after it, in diminishing order of susceptibility, *Br. melitensis*, *Salm. typhi*, *Salm. typhi-murium* and *Sh. flexneri*. Gastric juice and washings are also bacteriostatic for *Myco. tuberculosis* (Schwartz 1945, Kramer 1946).

With a view to understanding its significance in defence, Goldsworthy and Florey (1930) studied the distribution of Fleming's lysozyme in mucus and mucosal extracts of the stomach and intestines from several animal species, using as test organisms *Micrococcus lysodeikticus* and a series of unidentified susceptible bacteria isolated from the air of the laboratory. In the cat, no lysozyme could be detected in mucus from the stomach or colon, though small amounts could be demonstrated in saline extracts of the dried mucosæ. In the dog, detectable amounts were present in the mucosa of the intestinal tract, more in the colon than in the stomach. In the rabbit, the mucosal extracts were actively lytic. The colon was more active than the stomach, the small intestine falling between the two. In the guinea-pig, on the other hand, the mucosa from the stomach was more active than that from the intestine. What part this substance plays in eliminating susceptible species from the intestinal flora it is, however, impossible to say.

Quite apart, however, from the action of the contained lysozyme, there can be no doubt that the mucus itself provides a very efficient and important cleansing and protective mechanism. Florey (1933) found that the mucus does not form a uniform coating over the epithelial cells of the mucosa, but is present in the form of a lace-like network spread over the mucosal surface. The villi free themselves from any small adherent particles by movements that bring the particles into contact with the mucus, to which they adhere.

Solution B:	
phenol	5 gm.
distilled water	95 ml.

Mix the two solutions in the above quantities

Ammonium Oxalate Crystal Violet (Hucker).

Solution A	
crystal violet (90% dye content)	2 gm
ethyl alcohol (95%)	20 ml.

Solution B.	
ammonium oxalate	0.8 gm.
distilled water	80 ml

Mix the two solutions in the above quantities

Safranin

safranin (2.5% solution in 95% alcohol) . . .	10 ml
distilled water	100 ml.

Albert's Diphtheria Stain (Laybourn)

toluidine blue	0.15 gm
malachite green	0.02 gm.
acetic acid (glacial)	1 ml.
ethyl alcohol (95%)	2 ml
distilled water	100 ml

Preparation of Smears. Slides should be clean and free from all grease, and may be cleaned in soap and water, thoroughly rinsed, and stored in alcohol or xylol. Before use a slide is passed through the bunsen burner flame two or three times. A drop of distilled water is placed on the cooled slide and a small amount of bacterial growth suspended in it, spread and allowed to dry in air. The film is then fixed by passing through the burner flame two or three times, or, for some stains, by immersion in absolute methyl alcohol, glacial acetic acid or other fixatives.

Procedure of the Simple Stain. The fixed smear is covered with stain, allowed to stand for 30 to 60 seconds, rinsed off with tap water, excess water removed by blotting and allowed to dry in air. Bacteria are usually examined under the oil immersion objective, and the oil can be placed directly on top of the smear.

The Gram Stain. Of the differential stains, the Gram stain is one of the most valuable and most generally applied. The procedure is essentially one of staining with crystal violet, mordanting with iodine solution, decolorizing with alcohol and counterstaining with a dye of contrasting color. The stain was originally developed by the histologist Gram in an effort to stain bacteria in tissues differentially, and has been subject to many modifications. By this procedure bacteria are separated into two groups, those which retain the crystal violet and are said to be *gram-positive*, and those which are decolorized and stain with the counterstain which are *gram-negative*. The distinction is not always sharp for there is considerable variation in ease of decolorization, some gram-positive bacteria such as the pneumococcus become gram negative after they die, and some bacteria are gram variable. This last group is not large enough to detract from the practical value of the stain.

The Mechanism of the Gram Stain. Both the crystal violet and the iodine are highly specific while the alcohol and the counterstain are not. Almost all other dyes, even methyl green which differs by only one methyl group from crystal violet, are unsuitable, either being retained or removed by alcohol whether or not the iodine is applied. A few other reagents, notably

passages with an efficiency of 87.5 per cent. The efficiency was less—62.0 per cent.—when air containing only droplet nuclei was tested. The smaller the particle, and the slower the rate of inspiration, the more readily does it pass the nasal filter (Boyland *et al.* 1947; see also Druett *et al.* 1953, Harper and Morton 1953).

Whether mechanical clearance is the only factor concerned is again uncertain. Arnold, Ostrom and Singer (1928) introduced *Chromobacterium prodigiosum* and *Bact. coli*, by spraying, into the nose of men, rabbits, dogs and guinea-pigs, and noted their rapid disappearance. They state that swabs taken from the posterior pharyngeal wall gave no indication that there was any extensive passage of the bacteria to the throat; but they were unable to detect in nasal washings or secretions any substance that was bactericidal to the test organisms employed. It may be noted that the rate of disappearance recorded by Arnold and his colleagues—a diminution in numbers during the first 5 minutes, and total disappearance within half an hour—was more rapid than that recorded by Bloomfield—little change in 2 hours but almost complete disappearance in 24. This slower rate of elimination was also noted by Bloomfield in the case of particles of kieselguhr placed on the nasal septum. The route followed by substances introduced into the nose to some extent depends on the animal tested, the nature of the substance and the method of its administration. Rake (1937), for example, records a ready intercellular penetration of the olfactory mucosa of mice by pneumococci, *Salm. enteritidis*, particles of Prussian blue and the virus of equine encephalomyelitis, but only slow penetration by rabies and certain other viruses. In rabbits, virulent pneumococci penetrate the nasal mucosa only if the containing fluids are kept in prolonged contact with it (Cannon and Walsh 1937).

Lysozyme is known to be present in high concentration in the nasal secretions, and it is probable that it plays a part in freeing the nasal cavities from those species of bacteria against which it is active. A substance resembling Dold's inhibine in bactericidal power has been described in the nasal secretion of normal persons (Ignatius 1936). Burnet, Lush and Jackson (1939) found a heat-labile, possibly enzymic, substance in nasal secretion that inactivated certain viruses, notably those of influenza, herpes and poliomyelitis. Vaccinia virus was insusceptible to its action. (See also Francis and Brightman 1941.)

Whatever may be the nature of the complex of mechanisms involved there is every reason to suppose that the same result is attained in the nose as in the mouth. The majority of bacteria that enter at the external nares are removed or destroyed, and fail to obtain any but the most transient footing among the normal nasal flora; those that survive and multiply do so because they are in some way adapted for successful colonization, and once such colonization has occurred they may persist for an indefinite period (see also Chapter 90).

The conditions in the nasopharynx have been sufficiently dealt with in considering the elimination of bacteria from the mouth.

It would appear (Calamida and Bartarelli 1902) that the accessory nasal sinuses are normally sterile.

There is little doubt that in health the trachea and bronchi contain few if any living bacteria (see Thomson and Hewlett 1896, Bloomfield 1922*d*); and it is probable that the main protective mechanism consists in the filtering action of the nasal passages combined with the adherence of bacteria which pass the posterior nares, or are drawn in *via* the mouth, to the pharyngeal or upper laryngeal mucosa. It is, however, quite certain, from the ordinary experience of the post-mortem room, that dust particles, and hence presumably bacteria, reach the lungs in numbers that, if minimal in any short period of time, attain a considerable total in the course of months or years.

Under certain conditions, mainly experimental (see Nenninger 1901, Paul 1902,

HgCl₂, may be substituted for iodine, and stannous chloride, pyrogallol and freshly prepared solutions of hydroquinone show some slight activity.

However arbitrary Gram's method of staining may appear, the reaction is apparently associated with fundamental differences between the gram-positive and gram-negative organisms. There is, for example, a pronounced correlation between it and resistance to the bacteriostatic action of certain dyes and antibiotic substances, and to the action of other chemical and physical agents. The nature of the gram reaction has, therefore, been of considerable interest and three general types of theories to explain the differential staining have been developed.

(1) The theory of differential membrane permeability was proposed by Benians,³ whose experimental evidence was consistent with the view that while the cell membrane of both gram-positive and gram-negative bacteria is permeable to the crystal violet and iodine reagents, that of the former is not permeable to the alcohol-soluble dye-iodine complex and hence the color is retained.

(2) The colloidal chemical theory was advanced by Stearn and Stearn⁴ who postulated a relationship between the isoelectric point of the cell protoplasm and its affinity for basic dye on the basis of the negative response of gram positive bacteria at acid pH's, and related evidence; the isoelectric point of gram-positive bacteria is at a lower pH than that of the gram-negative bacteria and therefore the former have a stronger affinity for the basic dye.

(3) A morphological theory was developed principally by Churchman.⁵ His evidence strongly supported the view that the protoplasm of all bacteria is gram-negative and that the gram-positive forms are covered by a sheath or envelope of gram-positive material, i.e., the gram-positive cell consists of a gram-negative "medulla" and a gram-positive "cortex."

More recent work has substantiated this third hypothesis. Henry and Stacy⁶ were able to remove an outer layer from gram-positive bacteria by treatment with bile to leave a gram-negative cell or "cytoskeleton." The bile extract, not in itself gram-positive, contained protein, polysaccharide and the magnesium salt of ribonucleic acid. This material could be deposited on the surface of the extracted cells to render them gram-positive again, but could not be deposited on normally gram-negative bacteria. The ribonucleate appeared to be highly specific in that related compounds or other salts of ribonucleic acid could not be substituted for it. This work has been confirmed and extended by Bartholomew and Umbreit⁷ who converted gram-positive bacteria to gram-negative forms by digestion with ribonuclease and, further, were able to replace the bacterial ribonucleate with magnesium ribonucleate prepared from yeast. There was also evidence that the sulfhydryl groups of the protein were involved in some way in the gram reaction as a whole.

⁶ Henry and Stacy. *Nature*, 1943, 151:671

⁷ Bartholomew and Umbreit *Jour. Bact.*, 1944, 48:567 This paper includes a critical review of the pertinent literature.

species—resulting from localized glandular secretions, or from differences in the amount of moisture in the skin. Thus, the fluid part of human semen contains an inhibitor of *Staph. aureus*, but not of *Bact. coli* (Rozansky *et al.* 1949).

The urethra in the male and female is normally sterile, or contains in the neighbourhood of the meatus a few staphylococci and diphtheroid bacilli. The mechanical flushing action of the urine, combined perhaps with its slightly acid reaction (pH 6.0), is probably an important factor. Dold and Deck (1941) describe a heat-stable type of inhibine in fresh urine, active against a wide variety of pathogenic species. Both Dold (1947) and Björnesjö (1951) describe inhibitors of *Myco. tuberculosis* in normal urine. Björnesjö's substance is heat-stable, dialysable through cellophan, and is antagonized by serum albumin. Tamm and Horsfall (1952) isolated mucoprotein from urine of molecular weight of about 7 million, highly reactive with influenza, mumps and Newcastle viruses, inhibiting their hæmagglutinating activity; its significance in antiviral defence is not clear.

Urine contains lysozyme, which presumably could prevent the growth of lysozyme-sensitive organisms; a high lysozyme content is found in nephrotic children (Wilson and Hadley 1950).

The vagina has a highly characteristic flora, consisting largely of aciduric bacilli of the Döderlein type (see Küster 1929, Schultheiss 1929). The normal vaginal secretion has a marked bactericidal action on many species of bacteria. Thus Menge (1894) found that *Ps. pyocyanea*, staphylococci and streptococci introduced experimentally into the vagina could not be recovered after 21 to 26 hours (see also p. 1390).

Antibacterial substances have been described in cows' milk, active against cocci and coliform bacilli (see Hobbs 1939, Morris 1943, 1945, Green and Pauli 1943, Wilson and Rosenblum 1952, and pp 194, 2316). It is possible that in man such substances contribute to the defence of the lactating mammary gland against certain infections.

The Efficiency of the Bactericidal or Inhibitory Mechanisms Operating on Body Surfaces.

It is extremely difficult to assess the relative protective value of the factors that we have described above, as compared with the mechanisms that we shall discuss in subsequent chapters. It is obvious that they often fail; but how frequently they succeed we cannot tell.

TABLE 67

SHOWING THE PERCENTAGE MORTALITIES OBSERVED IN GROUPS OF MICE AFTER THE ADMINISTRATION OF VARIOUS DOSES OF A VIRULENT STRAIN OF *Salm. typhi-murium* INTRAPERITONEALLY OR *per os*.

Number of Bacilli administered.	Mortality per cent.	
	Intraperitoneal.	<i>Per os</i> .
1,000,000,000	Not tested	48.75
10,000,000	98.8	28.25
100,000	84.7	22.50
1,000	65.9	15.00
10	28.2	Not tested

The gram reaction, therefore, appears to depend on a surface structure of magnesium ribonucleate combined with protein which is present on gram-positive bacteria but lacking on gram-negative bacteria. This explanation is consistent also with the evidence brought forward by others but interpreted differently; for example, the reaction between the crystal violet and iodine reagents and the ribonucleate-protein complex does not occur at acid reactions, hence the reversal of the gram-positive reaction by lowering pH.

Procedure of the Gram Stain. In addition to crystal violet and safranin staining solutions, Lugol's iodine solution is required as a mordant. Its composition is

iodine	1 gm.
potassium iodide	2 gm.
distilled water	300 ml.

The staining procedure is as follows.

- (1) The heat fixed smear is stained for 1 minute with ammonium oxalate crystal violet.
- (2) Wash in tap water.
- (3) Flood with Lugol's iodine solution and allow to stand 1 minute.
- (4) Wash in tap water and blot dry.
- (5) Decolorize 30 seconds with gentle agitation in 95 per cent alcohol, and blot dry.
- (6) Counterstain 10 to 30 seconds in safranin.
- (7) Wash in tap water, blot dry and examine.

✓ **Acid-Fast Stain (Ziehl-Neelsen Method).** Certain bacteria, characterized by a high lipid content, cannot be stained by the usual procedure of the simple stain and either heat or prolonged contact is required to drive the stain into the cells. Conversely, the stained forms are equally difficult to decolorize and resist decolorization with acid alcohol. These organisms are designated acid fast and include the tubercle bacilli and related forms, the leprosy bacillus and certain of the actinomycetes.

Staining Procedure:

- (1) Stain the smear for 3 to 5 minutes in steaming Ziehl's carbol fuchsin. An alternative procedure useful in diagnostic laboratories is to stain in the cold for 18 to 24 hours.
- (2) Rinse in tap water.
- (3) Decolorize in 95 per cent ethyl alcohol, containing 3 per cent by volume of concentrated hydrochloric acid, until only a suggestion of pink color remains.
- (4) Wash in tap water.
- (5) Counterstain for 30 to 60 seconds with alkaline methylene blue.
- (6) Wash in tap water, dry and examine.

Fontana Stain for Spirochetes. The spirochetes stain very poorly or not at all by the usual simple staining procedure, and are usually stained by a silver impregnation method

add, drop by drop, enough more of the silver nitrate solution to produce a slight cloud which persists after shaking. This solution is stable for some months.

Staining Procedure:

- (1) Steam the heat fixed smear in a solution of 5 per cent tannic acid in 1 per cent phenol for 30 seconds.
- (2) Wash for 30 seconds in running water.
- (3) Flood with ammoniacal silver nitrate solution, heat gently, and allow to stand 20

Capsule Stain (Hiss's Method). The bacterial capsule does not stain in the simple stain or Gram stain procedures. A number of methods of staining the capsules have been used of which that of Hiss is one of the most simple and effective. The stain is an aqueous solution of basic fuchsin or crystal violet, 0.15 to 0.3 per cent and 0.05 to 0.1 per cent respectively.

Staining Procedure. The bacteria should be grown in ascitic fluid or serum medium for maximum capsule development, and bacteria grown on solid media should be suspended in serum for preparation of the smear. The smear is air dried and fixed by heat.

- (1) Stain with either aqueous basic fuchsin or aqueous crystal violet by heating gently until the stain steams.
- (2) Wash off the stain with 20 per cent aqueous copper sulfate solution.
- (3) Blot dry and examine.

The bacterial cells are deeply stained and the capsules a faint blue or pink, depending upon which stain has been used.

Spore Stain. Like acid-fast bacteria, spores are very difficult to stain and appear as unstained in the usual stained smear. The stain may be driven in by heat, and the Ziehl-Neelsen acid fast staining procedure may be used with the modification that decolorization is less rigorous, i.e., 95 per cent alcohol or absolute acetone should be used instead of acid alcohol.

CULTURE OF BACTERIA

Methods of Obtaining Pure Cultures. When fluid culture media are inoculated with substances such as soil, water or excreta, many kinds of organisms develop simultaneously side by side, and a heterogeneous mixture, or mixed culture, of bacteria results. Any technical procedure for obtaining such pure cultures is dependent upon the isolation of a single viable bacterium which is allowed to multiply in a suitable culture medium. The first reliable method of isolation of pure cultures was devised by Koch in 1881. This method has proved so satisfactory that it has been employed to the present day with only minor modifications. If nutrient gelatin or agar is inoculated while fluid (for example, at 42° C.) and is then solidified and kept under favorable temperature conditions, many of the living bacteria that have been introduced are able to multiply. Since the bacteria cannot move about freely, but are fixed in the stiffened medium, the progeny of each organism form distinct masses or colonies. These colonies consist of many millions of bacteria and are readily visible to the naked eye or by means of a low power hand lens. If the colonies are not closely crowded, a pure culture may be obtained by touching a colony with the tip of a sterile needle and inoculating tubes of fresh culture media. In order to secure a large surface upon which the colonies shall be spread out and made easily accessible, the gelatin or agar after inoculation is poured while still fluid into sterilized flat shallow dishes (petri dishes) fitted with glass covers.

It will be clear that a given colony may arise from two or more parent cells if these remain attached or close together in the agar medium, and the colony will not be a pure culture in the event that the juxtaposed cells are of different species. This possibility has been investigated by McNew* using the plant pathogen *Phytophthora stewartii*. He found that 98 per cent or more of the colonies arose from single cells, hence the probability of a mixed culture in a single colony is 0.02 or less. Successive plating or picking a number of colonies

* McNew. *Phytopathology*, 1938, 28: 387.

to the stimulus provided by the toxin in the infected tissues by a rapid and copious outpouring of antitoxin (the "secondary response"; see Chapter 50); so that the toxin production by the bacterium is more than counterbalanced by the antitoxin production in the host. The 0.01 unit per ml. level is an unreliable index of immunity for two reasons. Firstly, the protective value even of passively administered antitoxin, when there is no question of a later secondary response, varies widely from individual to individual in both man and animals. Thus for a given dose of toxin, the amount of antitoxin required to protect each of an apparently homogeneous group of rabbits may vary over a 100-fold range (Ipsen 1946). Secondly, there is no necessary connection between the serum level and the degree of secondary responsiveness upon which active immunity largely depends. Similar levels might occur in persons whose primary conditioning—for example by a mild infection—was feeble, and in persons with a high degree of responsiveness due to recent immunization (see, *e.g.*, Barr and Glenny 1945, Ipsen 1946). Moreover, the invasiveness and the toxigenicity of the infecting bacilli, and the number in which they arrive at the susceptible tissue, may be such as to overwhelm even a high degree of specific immunity. With these reservations in mind, however, we may regard 0.01 unit per ml. as an average level above which we should attempt to raise the non-immune. The higher it is raised by active immunization, the less likely is infection to result in disease, and the smaller is the probability of complications or death in those who do contract it (Ipsen 1946, Hartley *et al.* 1950.)

Although deviations from this roughly quantitative relation can be attributed mainly to variations in the animals' resistance or the severity of the infective attack, it is possible that differences between one antitoxin and another affect the firmness of toxin-antitoxin union, and so the degree of protection afforded.

We saw in Chapter 7 that antitoxins varied greatly in avidity for toxin; and it is natural to suppose that a relatively feeble combining power would be associated with a low protective power *in vivo*. It should be noted, however, that highly avid sera are usually produced by prolonged immunization of a kind designed to yield high-titre antitoxins; and although it is entirely proper to insist that antitoxins for passive serum treatment of diphtheria should have both qualities, we do not know whether avidity is necessarily an effective quality of the low-titre antitoxins that occur naturally in man.

The increased resistance afforded by specific antitoxic immunity is determined almost entirely by the interception and neutralization of the toxin before it reaches the susceptible cells. Once these have been attacked, the antitoxin is relatively ineffective.

Glenny and Hopkins (1925) studied the effect of various doses of antitoxin at different times after the intradermal injection of a Schick dose of diphtheria toxin into a guinea-pig. This amount of toxin produces a characteristic local reaction at the site of inoculation; 0.001 unit of antitoxin is sufficient to prevent this reaction when the toxin and antitoxin are mixed together before inoculation. When, however, the toxin is injected before the antitoxin, neither 10 units of antitoxin injected intravenously 15 minutes later, nor 1,000 units injected intravenously 30 minutes later, are sufficient to prevent the appearance of a small reaction at the site of the injection of the toxin. The reaction is, however, much smaller than that which occurs when no antitoxin is given. When 10 units of antitoxin are administered intravenously 30 minutes after the intradermal injection of the toxin, or 1,000 units intravenously after 1½ hours, or intramuscularly after 45 minutes, the lesion is reduced to about half its usual diameter. A slight reduction in the size of the reaction is obtained when 1,000 units are injected intravenously after 2½ hours, or intramuscularly

makes a pure culture a practical certainty. It is likely, however, that this figure differs for different bacteria, *i.e.*, staphylococci are more likely to remain attached than micrococci or bacilli.

It is self-evident that the pure culture so obtained is not only homogeneous with respect to kind or species of bacteria, but since the microorganisms are descendants of a single parent cell, they constitute what the zoologist or protozoologist terms a *clone*.

Technique of Making Plate Cultures. Three tubes of agar (1, 2, 3), melted at 100° C., are placed in a water bath at 42° C., a temperature that is just above the solidifying point of agar and is not injurious to bacteria. Tube 1 is inoculated with a loopful of the material to be plated. The cotton plug is then replaced and the contents of the tube are mixed by carefully tilting back and forth and rotating the tube on its long axis. From this tube two loopfuls of agar are transferred to tube 2, and after mixing, two more loopfuls carried from tube 2 to tube 3. The contents of the several tubes are then poured into petri dishes. As soon as the cotton plug is removed, the mouth of each tube should be passed through the flame and inserted under the edge of the lifted petri dish cover, and the agar quickly poured out. The covered petri dish may then be tipped cautiously back and forth to distribute the agar evenly before it solidifies. Agar plates placed in the incubator after solidification should be inverted in order to avoid spreading of the growth through condensation of moisture on the surface of the medium. Even if there are a great many bacteria in the original material, the plate from tube 3 will probably contain the organisms in small enough numbers to develop well isolated colonies. On the other hand, if there are very few bacteria in the material inoculated, plate 1 will probably present more satisfactory conditions. Gelatin plates are made in the same manner as agar except that gelatin may be cooled as low as 25° C. without solidifying.

Under exceptional conditions, such as work in the field, when petri dishes are not available, so-called "roll tubes" may be made. The tubes containing the liquid agar medium are tilted until the agar almost reaches the cotton plug. The tubes are then rotated in this position against a block of ice, and when the process is complete the test tube is coated on the inside with a thin layer of solid medium. In this way a considerable surface is obtained and, after incubation, colonies are readily picked.

Quantitative Dilution. It is sometimes of advantage before plating to make accurate

(A)	To dilute 1	10	use 1 ml. of sample to	9 ml. of sterile water.
(B)	" 1	100	" "	" " " "
(C)	" 1	1,000	" "	(A) " " " "
(D)	" 1	10,000	" "	(B) " " " "
(E)	" 1	100,000	" "	(C) " " " "
(F)	" 1	1,000,000	" "	(D) " " " "

One milliliter of each dilution is placed in a sterile petri dish and 6 to 8 ml. of liquid cooled agar medium are added. The two are thoroughly mixed by tilting the petri dish back and forth and then allowed to solidify. After incubation the total number of colonies on the plates containing 50 to 200 colonies is counted and the total number is multiplied by the dilution to give the number of organisms present in the original sample. Such bacterial counts are relatively inaccurate, errors of 10 to 15 per cent being common in even the most careful work, and must be regarded only as useful approximations.

Streak Plates. Not infrequently media used for the isolation of the more fastidious bacteria are such that it is technically difficult to make the usual pour plates. The most common of these media are those which contain fresh blood. Such media are ordinarily prepared in quantity and sterile plates poured. These may be stored in the ice box until

toxin plays any important part in the invasive process, the antitoxin might to that extent lessen the infection. But we should expect modification of the infection rather than complete immunity. The available evidence is in accord with our expectations.

As regards diphtheria, we discuss in Chapter 61 the evidence for other toxic components of *C. diphtheriae*, which antitoxins as usually prepared fail to neutralize. There are clinical indications that immunity may be referable to bacterial antigens other than the toxin. Thus, nurses in fever hospitals with no detectable antitoxin remain healthy in the face of a continuous risk of diphtheria, suggesting that they may have an *antibacterial* immunity. Lack of such immunity may also explain the not uncommon occurrence of diphtheria in persons with a high antitoxin level; and although in some of these cases the diphtheritic patients may be exhibiting a secondary response to the toxins produced in the early stages of their disease (see Hartley *et al.* 1950), for others this view is not tenable. Indeed, in the light of the recent demonstration of the heterogeneity of purified diphtheria toxin, we are in no position to assert that effective antitoxic sera owe their efficacy to antitoxin alone; or that toxoid is the only protective antigen in diphtheria prophylactics. Toxins from *C. diphtheriae* appear to be homogeneous in that they are all specifically neutralized by a single antitoxin; but strains differ in their somatic antigens (see Hewitt 1948). Frobisher and his colleagues report in rabbits an increase in resistance to toxigenic *C. diphtheriae* which, after immunization with avirulent non-toxigenic strains, was associated with greater tissue reactivity to injected bacilli. No antitoxin was detectable in the partly resistant animals, and the resistance was to some extent associated with serological type-specificity (Frobisher and Updyke 1947, Frobisher and Parsons 1950).

The presence of circulating antitoxin, active against the rash-producing toxin of the hæmolytic streptococcus, affords protection against clinical scarlet fever, that is, against the obvious effects of the toxin itself; but it does not appear to protect against the local lesion in the throat—the acute tonsillitis (Okell 1932). Again, it would seem (Burt-White, Colebrook and others 1930, Baird and Cruickshank 1930, Stent 1930) that the presence of circulating antitoxin, as revealed by a negative Dick test in pregnant women during the later stages of gestation (see p. 1676) affords little if any protection against a severe or fatal infection with hæmolytic streptococci during the puerperium. These clinical findings are borne out by the results of experiment. Thus, Parish and Okell (1927) found that a potent antitoxic serum, which would protect rabbits against acute toxæmic death following the intravenous injection of large doses of living cultures of hæmolytic streptococci, did not prevent a fatal infection, leading to death after a week or more, associated with multiple foci of infection. Nevertheless, as reference to Chapter 66 will show, in patients with scarlet fever, antitoxic sera sometimes appear to influence the course, not only of the toxæmia, but of complications directly referable to the bacterial invasion by the *Str. pyogenes*.

Closely analogous results were obtained in experimental staphylococcal infections in the rabbit (Burnet 1929, Burnet and Kellaway 1930, Kellaway, Burnet and Williams 1930). The potent staphylococcal toxin is neutralized, in constant proportions, by the specific antitoxin; and a rabbit can be actively or passively immunized against the poisonous effect of a toxin-containing filtrate. But such immunized animals are still susceptible to the injection of living staphylococci and succumb to a pyæmic infection, though they survive rather longer than non-immunized controls. Later studies, however, indicate clearly that in rabbits antitoxin protects, though not completely, against bacterial invasion. Ramon and his colleagues (1936*a, b*) found that intravenous virulent *Staph. aureus* did not kill rabbits with a high level of antitoxin in the serum, whereas rabbits with a low level succumbed. Kitching and Farrell (1936) observed that immunization with toxoid protected rabbits against infection, but that immunization with bacterial bodies, though it produced abundant agglutinins, was ineffective. Both Forssman (1936) and Smith (1937) demonstrated that active immunization with staphylococcal products was

There are four general categories which, in the order of the fineness of distinction they make possible, are: (a) morphology, both gross and microscopic; (b) physiologic capabilities in terms of biochemical reactions; (c) pathogenicity for experimental animals; (d) immunologic character.

The preliminary and basic study of a bacterium lies in the systematic determination of its cultural characters. The most important of these are:

(A) Morphology

1. gross morphology—that of colonies of the organism with respect to size, texture, color, shape, etc.
 - (a) on nutrient or infusion semisolid media
 - (b) on special media
2. microscopic morphology, including
 - (a) size, shape and grouping of the organisms
 - (b) presence or absence of spores
 - (c) motility
 - (d) presence or absence of capsule
 - (e) staining reactions

(B) Biochemical reactions

1. the fermentation of sugars, usually dextrose, lactose and sucrose, although others may be included together with the hydrolysis of starch
2. liquefaction of gelatin
3. formation of indol
4. reduction of nitrate to nitrite
5. production of hydrogen sulfide
6. special biochemical tests such as the Voges-Proskauer reaction, the methyl red test, hemolysis on blood agar, etc.

Such preliminary examination ordinarily affords a great deal of information about a given bacterial culture. The feasibility of additional study rests firmly on the foundation laid down by the studies outlined above.

Various attempts have been made to systematize the study of bacteria. One of the most successful of these has resulted from the efforts of a Committee on Bacteriological Technique of the Society of American Bacteriologists, under whose auspices a Manual of Pure Culture Study has been published and is supplemented by leaflets from time to time. Through this agency standard methods and descriptive terminology are made available. Furthermore, the same committee has prepared a standard descriptive chart for the recording of data, and from time to time the chart is revised.

ANIMAL INOCULATION

An indispensable adjunct to the study of the pathogenic bacteria is the experimental animal. Animals are used not only for the study of the pathology of infectious disease and as an aid in the isolation of some bacteria in pure culture, but also for the experimental production of immune sera and studies on the various manifestations of immune phenomena. The maintenance of such infectious agents as the filterable viruses, which cannot be cultivated on lifeless media, by animal passage is common also. The animals generally used are rabbits, guinea pigs, white mice and white rats, although in special cases others, such as rhesus monkeys, are necessary.

Routes of Inoculation. Experimental animals may be inoculated by a variety of routes, usually one or another being preferable under the particular cir-

most active of the sessile histiocytes are those found in certain specialized regions of the vascular or lymphatic endothelium—the liver capillaries (Kupffer cells), the spleen sinuses, the venous sinusoids of the bone-marrow, the capillaries and medullary sinusoids of the adrenals, the capillaries of the pituitary gland, and the sinuses of the lymph glands throughout the body. Somewhat less active in this respect are the reticuloocytes, which are not part of the lining to blood or lymphatic channels, but are disposed about the reticulum fibres in the interstices of the tissues. The wandering histiocytes are found throughout the tissue spaces, and some of them find their way into the circulating blood, particularly into the vessels of the internal organs.

The common character of dye-storage possessed by cells of this type led many observers, and particularly Aschoff (1924), to regard them as an integrated system of cells fulfilling a particular bodily function. Aschoff coined for them the name *reticulo-endothelial system* (R. E. system). The cells of this system may be classified as follows :

The schema classifies the various cells belonging to the system, and does not necessarily represent a genealogy of the cells found in the animal body. The interrelations of the cells in this schema are far from clear; but subsequent work has indicated some which are relevant to our discussion. The R. E. system is part of a larger system of connective tissue cells that participate in defence, and the reactions to infection consist not only of phagocytosis and digestion of the invading organism, but of development and proliferation of phagocytes from other mesenchyme cells. Many of the cells in the R.E. system have this developmental potentiality, but to these must be added cells not in the system, especially the non-phagocytic lymphocytes and plasma cells which may also give rise to macrophages (Rebuck 1947). Taliaferro and Mulligan, indeed, substitute for the R.E. system the *lymphoid-macrophage system*, which contains all the potential and actual macrophage cells, including the non-granular leucocytes (see Taliaferro 1949). What we have to say in the following pages about the R.E. system is in general valid for the wider lymphoid-macrophage system. Both exclude, and are in contrast with, Metchnikoff's *microphage* connective tissue cells, namely the granular polymorphonuclear leucocytes. For our purpose the R. E. system is a functional unit consisting of cells derived from the mesenchyme, having in common a phagocytic activity (see, for example, Doan 1940). We are particularly concerned with

The Reactions which follow the Intravenous Injection of Bacteria into Normal Animals.

There is no doubt at all that the mechanism brought into play in clearing the blood stream from bacterial cells is in the main identical with that which frees it from inert particles of the same order of size (Wyssokowitch 1886, Werigo 1894, Opitz 1898, Bardach 1889, Métin 1900, Bail 1905, Bull 1914-16, Kyes 1916, Bartlett and Ozaki 1917, 1918, Wright 1927 and many others). The reticulo-endothelial cells, particularly those of the liver, spleen and bone-marrow, actively phagocytose the injected bacteria. The mechanism of aggregation, followed by the removal of the bacterial aggregates from the general circulation by their retention in the lung capillaries, is sometimes very prominent (Bull 1914-16, Bartlett and Ozaki 1917, 1918, Wright 1927, Dudgeon and Goadby 1931). This is accompanied, as in the case of the intravenous injection of carbon particles, by an accumulation of polymorphonuclear cells in the lung capillaries, associated with a temporary peripheral leucopenia (see Levaditi 1901, Andrewes 1910). But the polymorphonuclear cells appear to play a more active part in phagocytosing bacteria than in phagocytosing carbon particles (Dudgeon and Goadby 1931). It is probable that these cells with their ingested bacteria are subsequently carried to the reticulo-endothelial depôts in the spleen, liver and elsewhere, and are there phagocytosed by the sessile histiocytes. Such wandering histiocytes as are present in the lung capillaries ingest the bacterial cells, or cell-aggregates, directly.

So far then as we can regard bacteria merely as foreign particles, our description of the reaction of the tissues to the intravenous injection of vital stains or carbon particles needs little modification. But, in fact, the bacteria we inject are alive and capable of multiplication; and it is the balance between their capacity to multiply and the capacity of the tissues to remove them that determines the fate of the animal host.

Bull (1914-16) counted the viable pneumococci and streptococci in the systemic blood stream of dogs and rabbits at various intervals after the intravenous inoculation of a bacterial suspension. There was at first a sharp and progressive fall in the number of organisms in the circulating blood, lasting until about the 5th hour; then a secondary rise, varying in degree and persistence with the virulence of the organism and the resistance of the host. With strains of low virulence the numbers then declined until the blood became sterile. With typhoid bacilli the fall in numbers was very rapid, from 10,000,000 per ml 1 minute after injection to 40 per ml. at the end of 15 minutes.

Wright (1927) made a detailed study of pneumococcal septicæmia in the rabbit, and the following examples are taken from his paper.

TABLE 68

LIVING PNEUMOCOCCI PER ML. OF CIRCULATING BLOOD AT STATED TIMES AFTER INOCULATION OF AVIRULENT, SLIGHTLY VIRULENT, AND HIGHLY VIRULENT PNEUMOCOCCI INTO NORMAL RABBITS.

Time	Avirulent.	Slightly Virulent.	Highly Virulent.
Immediately	8,900,000	1,030,000	1,070,000
2 hours	206	20,800	137,000
5 "	2	340	25,000
24 "	0	1,300	1,510,000
48 "	—	134	Dead
96 "	—	0	—

es. The common routes of inoculation are intradermal, subcutaneous, intracuticular, intraperitoneal and intravenous. Other routes such as intracerebral, intrathecal, etc., may be desirable at times. In any case, inoculation is carried out with a syringe and hypodermic needle, the capacity of the syringe and size of the needle used depending upon the quantity of material to be injected and the route of inoculation. The site of inoculation should be prepared by removal of the hair by shaving or a depilatory, followed by disinfection by swabbing with alcohol, tincture of iodine, etc. The syringe and needles have, of course, been previously sterilized by dry heat or by boiling.

Intracutaneous Inoculation. Material inoculated intracutaneously is inoculated into the dermis. A fold of skin is pinched up and the needle inserted, lumen up, as superficially as possible. A raised white spot showing the pits of the hair follicles indicates a successful inoculation. Not more than 0.2 ml. may be inoculated by this route.

Subcutaneous Inoculation. Subcutaneous inoculation requires considerably less skill than the part of the operator. A fold of skin is pinched up as before and the needle inserted through the skin to its full length. The injected material forms a bleb or blister. The amount that may be injected by this route depends upon the size of the animal.

Intramuscular Inoculation. In the intramuscular inoculation, the needle is inserted deep into the muscular tissue, usually the posterior muscles of the thigh or the lateral thoracic or abdominal muscles.

Intraperitoneal Inoculation. Intraperitoneal inoculation is carried out as one would a subcutaneous injection on the abdomen except that after the needle penetrates the skin, it is held at right angles to the peritoneal wall and thrust through into the peritoneal cavity.

Intravenous Inoculation. Intravenous inoculation may be carried out in a variety of ways, the choice depending upon the size of the animal. Rabbits are conveniently inoculated in the marginal vein of the ear. The needle is inserted through the skin and into the vein from the side. If the needle is within the vein, blood will disappear in the vein from the point of the needle onward as the material is injected. Needless to say, the injection should take place in the direction of blood flow. Guinea pigs may be inoculated into the large superficial vein on the dorsal and inner side of the hind leg or into one of the external jugular veins. Both require anesthesia of the animal and a small incision, which may be later closed with a suture or collodion. Rats may be inoculated in an external jugular vein and mice in one of the lateral veins of the tail.

between the ribs at the point of maximum pulsation and thrust into the heart, taking care to injure the pericardium as little as possible. Blood is most conveniently taken from smaller animals by this means.

Postmortem Examination. The autopsy of experimental animals dead of infection is often highly desirable. Not only may cultures be taken, but the gross and microscopic pathology is usually of significance. The animal is fastened down on a board, ventral surface up. It is good practice to have the board in a larger enameled tray to reduce to a

or other changes, and the hair and skin are disinfected with cresol or lysol.

The skin is incised from the pubis to the neck and cut at right angles at the ends of the

bacterial growth (see Chapter 4). Wright showed that this initial clearance of virulent pneumococci can be almost eliminated by injecting a culture that is still in the logarithmic phase.

In the argument from analogy, which plays so large a part in the construction of our concepts of infection and resistance, we must be very careful to allow for the effects of our experimental technique. The reactions which we have described above are those that follow the sudden introduction into the blood stream of a relatively enormous number of bacteria—a number of the order of 1,000,000,000. Such an occurrence must be of extreme rarity in natural infection, and it is possible that some part of the mechanism we have described—for instance, the aggregation of bacterial cells and the retention of the aggregates in the lung capillaries—may have been over-emphasized by the particular experimental procedure that we have chosen to employ. In any case there seems little doubt that the most significant happenings in the primary bacteræmia are those that occur between the 5th and 24th hours after an intravenous inoculation, when the fate of the host is being determined by the balance between bacterial multiplication, on the one hand, and the removal of the newly produced bacterial cells on the other.

The increasing bacteræmia does not appear to be due to any exhaustion of the clearing mechanism. Martin and Kerby (1950) found that the removal of a strain of *Staph. aureus* from the blood of a rabbit suffering from an overwhelming and ultimately fatal pneumococcal bacteræmia was as efficient as that in a normal rabbit. There was no evidence that, in the overwhelming infection, the pneumococci had acquired a resistance to clearance from the blood stream.

Even when the tide has for the moment turned decisively in favour of the host, it does not follow that there will be a complete sterilization of the tissues. Bacteria will have been caught up in the liver, spleen and elsewhere, and may remain alive, but relatively inactive, for considerable periods. For example, in experimental infections of various rodents viable *Past. pestis* and bacilli of tularæmia may persist for several days in the tissues of animals that eventually recover (Meyer *et al.* 1948, Downs *et al.* 1949). In more chronic infections, like tuberculosis, the bacteria persist for much longer periods (see Brieger 1949).

Our knowledge of the exact method by which bacteria are killed in the tissues is woefully incomplete. There is no doubt at all that the majority of the bacteria taken up by phagocytic cells are destroyed by intracellular digestion; but the tacit assumption that a bacterium phagocytosed is, of necessity, a bacterium finally disposed of is certainly unwarranted.

It should be noted that clearance may be effected by the mediation of granulocytes. Braude (1951) for example, recorded the accumulation of polymorphonuclear cells containing brucellæ in the sinusoids of the liver, as well as phagocytosis by the sessile Kupffer cells, within 3 hours of intravenous injection of the organisms into mice; within 24 hours, the granulocytes were largely replaced by macrophages.

The Reactions that follow the Intraperitoneal Injection of Bacteria or of Suspensions of Inert Particles into Normal Animals.

The small quantity of fluid present in the normal peritoneal cavity, or other serous sac, contains very few cells, and these consist almost entirely of mononuclears, mainly of the lymphocyte type (Dudgeon and Ross 1906, Cappell 1930, and many others).

Durham (1897), in his classical paper on the reaction to intraperitoneal infection,

incision. The two flaps may be laid back by separation of the cutaneous from the underlying muscular tissue with a scalpel. The condition of the subcutaneous tissue and of axillary and inguinal lymph glands may be noted. The peritoneal fluid may be cultured by searing a small area on the surface of the abdomen with a hot spatula and puncturing with a syringe and needle or a Pasteur pipette into which the fluid may be aspirated. The abdominal cavity is opened with fresh instruments and the flaps are laid back as above. The condition of the abdominal organs, such as spleen and liver, may be noted and cultures taken by first searing the surface and then either puncturing and aspirating fluid with a syringe and needle or a Pasteur pipette, or by removing a small piece of tissue and placing it in nutrient medium. Likewise, pieces of tissue may be removed and placed in fixing fluid for subsequent sectioning. Again with fresh instruments, the costal cartilages are cut to make a V-shaped incision and this flap is laid back over the head, exposing the thoracic cavity. Any gross pathology may be noted, cultures may be taken from heart's blood and elsewhere if desirable, and pieces of tissue removed for fixation and sectioning. The animal is disposed of by incineration.

It is obviously impossible to define postmortem procedure rigorously. The lymphatic

The routine of examination will be determined, therefore, by the particular disease under consideration or, if this is not known, by the symptoms exhibited by the animal before death.

A number of precautions must be observed in the autopsy of animals dead of infectious disease. If cultures are to be taken, fresh sterile instruments must be used at each stage. Instruments once used should be returned to the boiling water sterilizer or placed in a tray containing lysol or, if to be used again, laid down on the edge of the tray with all sharp edges and points inward. Extreme care must be taken to avoid disseminating infectious

IMMUNOLOGICAL METHODS

The immunological or serological reactions serve to differentiate bacteria on the basis of their constituent antigens. Such immunological differences are usually, though not always, subordinate to the biochemical differentiation of species and in general serve to subdivide species into immunological types or varieties. The immunological identification of an unknown microorganism is of considerable diagnostic utility, and is frequently of very great value in epidemiological studies in tracing the source and dissemination of infection. Furthermore, serum may be tested against a known antigen to establish the presence of the homologous antibody and thus by inference the presence, immediate or past, of the microorganism or its products in the host, and therefore serves as an indirect diagnostic procedure. The specific neutralization of toxin by antitoxin *in vivo* serves to measure antibody in serum or the circulating antibody in the living host, and in the latter is a measure of antitoxic immunity. Of the *in vitro* immunological reactions, those of agglutination of a bacterial or other discrete antigen, precipitation of a soluble antigen, and complement fixation in the presence of soluble or discrete antigen are of general utility.

Titration of Diphtheria Antitoxin by the Römer Method. The intradermal inoculation of diphtheria toxin in the rabbit produces a local erythema, and central necrosis with doses, which may be used in the assay of toxin, and of toxin in the presence of antitoxin. The end point ordinarily taken is the smallest amount of toxin that, in a dose of 0.2

carrying with it, as in a retracted net, the particles caught on its surface layers. The mechanism of these movements was studied by Florey and Carleton (1926). They found that the omentum is totally incapable of any intrinsic movement. The movements that it undergoes are impressed on it by (a) posture, (b) the peristaltic movements of the intestines, and (c) the movements of the diaphragm. The retraction into a tightly gathered transverse band is due to the alteration in the character of the omental surface, and particularly to the deposition of fibrin, which causes the omental folds that are brought into apposition to adhere to one another, instead of extending again in response to the next passive movement.

The reaction that follows an intraperitoneal injection is not, however, limited to the peritoneal cavity. Indeed, it spreads beyond it with surprising rapidity.

Muscattello (1895) injected carmine suspensions into the peritoneum, killed the inoculated animals after various intervals, and studied the distribution of the dye. Within 1-2 hours he found particles of carmine in the liver and spleen. Similar particles, in smaller numbers, were found in the lungs, pancreas and testis. Durham (1897) noted the rapid passage of bacteria from the peritoneal cavity to the blood stream, and concluded that the most important route of transit was via the diaphragmatic lymphatics, the anterior mediastinal glands and the right lymphatic duct. The importance of the diaphragmatic route was also noted by Dudgeon and Ross, and the correctness of Durham's conclusions has been confirmed by many subsequent observers, notably in the careful studies of Buxton and his co-workers, and in the subsequent studies of Bolton (1921). Buxton and Torrey (1906b) found that, almost immediately after the intraperitoneal injection of an Indian-ink suspension, there was a rush of carbon particles into and through the lymphatics of the diaphragm. Thence they passed rapidly through the anterior mediastinal lymphatics and the corresponding lymph glands, reaching the blood stream within a very few minutes. During the earliest stages of this transit there was very little evidence of phagocytosis in the mediastinal glands or elsewhere; but, as time passed, an increasing number of carbon particles were found within the histiocytes of the lymph nodes.

In other experiments (Buxton 1906, Buxton and Torrey 1906a) the fate of living typhoid bacilli, injected intraperitoneally into rabbits, was followed by quantitative plating methods. The living bacilli passed into the general circulation almost immediately; and their numbers per ml. of circulating blood reached a maximum after about an hour. After this there was a rapid decrease, and few bacilli could be recovered from the blood after about the 6th hour. When suspensions of liver and spleen tissue were plated it was found that there was a rapid accumulation of bacilli in these organs, and particularly in the liver, within a few minutes after an intraperitoneal injection. There was then a transitory decrease in the numbers of viable organisms, followed by a secondary increase lasting from the 2nd to the 6th hour, i.e., the bacilli were increasing in the liver and the spleen while they were decreasing in the blood. After about the 6th hour there was a general decrease, lasting for several days, and more rapid in the liver than in the spleen. When animals were killed 4 days after injection viable bacilli were still recovered from the liver, though in small numbers; larger numbers were recovered from the spleen, and very large numbers from the mediastinal glands. Many observations on laboratory animals have shown that living bacilli may be recovered from the spleen weeks or months after experimental infection (Topley and Wilson 1923, Price-Jones 1927).

It may be noted that the rapid transit of particles or bacteria from the peritoneum to the blood stream is almost certainly the result of the mechanical pumping action of the rise and fall of the diaphragm in breathing. This is probably assisted by a special arrangement of the endothelial cells of the peritoneal membrane covering the diaphragm, which provides for a rapid passage of particles to the underlying lymphatics (Florey 1927; see also Bangham *et al* 1953)

ml, will produce a zone of erythema 10 mm. in diameter 48 hours after inoculation. This is designated the minimal reacting dose or MRD, and the activity of a toxin may be measured as MRD per ml.

Such a titration measures the potency or toxicity of the toxin preparation, but not its combining power with respect to antitoxin. An expression of the activity of the toxin in the presence of antitoxin is the definition of the Lr dose. This is that amount of toxin which, when mixed with 1 unit of standard antitoxin, contains 1 MRD of unneutralized toxin. It will be clear that a toxin so standardized with respect to standard antitoxin can then be used to titrate an unknown antitoxin by using a constant amount of toxin mixed with serial dilutions of the unknown antitoxin, and testing of the mixtures for activity.

One application of this technique is the titration of the antitoxin content of the serum of persons, immunized, convalescent or normal. This will be considered here since it illustrates all of the principles involved. In studies on human immunity the usual procedure is to titrate the serum against an amount of toxin which will just give the end point reaction when mixed with 0.002 units of standard antitoxin, this is commonly spoken of as titration at the 1/500th level.

Standardization of Toxin at the 1/500th Level. Toxins vary widely in potency and combining power and no precise quantitative procedure may be given. The general model of the titration is as follows:

- (1) Assume that a toxin whose L₊ dose is known is available. Then the following preliminary titrations can be carried out:
 - (a) The standard antitoxin is diluted so that it contains 1 unit per ml.
 - (b) The toxin is diluted so that it contains 1 L₊ dose per ml.
 - (c) The toxin is titrated in dilutions of 1:100, 1:200, 1:300, up to 1:1000 against constant amounts of antitoxin, viz., 1 ml. of diluted antitoxin is mixed with 1 ml. of each toxin dilution, incubated as indicated below, 0.2 ml. of each inoculated intradermally in the rabbit, and the reaction read in 48 hours. This titration determines the Lr dose of toxin.
 - (d) Additional preliminary titration indicates the approximate amount of toxin required to just give the skin reaction in the presence of 1/500 unit of antitoxin. A more precise determination is carried out as follows:
 - (i) Prepare a dilution of the original toxin in sterile broth to contain exactly 100 Lr per ml. This is the so-called stock solution and is relatively stable if prepared from stabilized (aged) toxin.
 - (ii) Dilute 1 ml. of the stock solution of toxin with 99 ml. of buffer solution to give a solution containing 1 Lr per ml.
 - (iii) Prepare serial dilutions at intervals of 5 within the limits indicated by the above preliminary titration. Thus, if the end point is indicated as lying between 1:40 and 1:80, prepare 1:40, 1:45, 1:50, up to 1:80.
 - (iv) Mix 1 ml. of each dilution of toxin with 1 ml. of standard antitoxin diluted to contain 0.002 unit per ml. Incubate the mixtures for 1 hour at 37° C. and leave in the refrigerator overnight to allow ample time for the toxin-antitoxin reaction.
 - (v) Inject 0.2 ml. of each dilution mixture intradermally into the shaven skin of a rabbit (as many as 40 such inoculations may be made in a single animal without ill effects) and identify the sites of inoculation with dye.
 - (vi) Read at 48 hours, the end point being that dilution of toxin which produces a zone of erythema nearest to 10 mm. in diameter.

Titration of Antitoxin at the 1/500th Level. For the titration of antitoxin in serum proceed as follows:

- (1) Dilute the stock solution of toxin as indicated in the above standardization, i.e., so that 1 ml. contains sufficient toxin to give the skin reaction when mixed with 1 ml. of antitoxin containing 0.002 unit per ml. and inoculated in amounts of 0.2 ml.
- (2) Prepare dilutions of patient's serum, say, for illustrative purposes, of 1:10 and 1:500.
- (3) Mix 1 ml. of undiluted serum and 1 ml. of each of the dilutions with 1 ml. each of the diluted toxin, and in addition set up a control which contains 1 ml. of the diluted toxin and 1 ml. of standard antitoxin diluted to contain 0.002 unit.

into play, but of the predilection of the bacterium for the tissues it is invading. Very little is known of the peculiarities, chemical or physical, of the bacterial surface that determines its affinities for a given cell or tissue, though several attempts have been made to relate virulence to qualities like surface charge (see Falk and Jacobson 1925, 1926, Jacobson and Falk 1927). Some progress has been made in recent years with the study of the special affinities that viruses have for sticking to certain types of cells (see Chapter 55); a similar study of bacteria might equally illuminate the pathogenesis of bacterial disease.

The Permeability of Blood and Lymph Capillaries to Foreign Matter.—Underlying the various epithelial surfaces of the body there is an extensive anastomotic network of blood capillaries and lymphatic channels. The two networks, with rare exceptions, constitute independent systems, each lined by a continuous sheet of endothelial cells. The lymphatic network drains into the afferent lymphatic channels, which in turn lead to a lymph node (Drinker and Yoffey 1941). In normal tissues, excepting the liver, the permeability of both capillary and lymphatic endothelium is poor. Substances of low molecular weight only are absorbed from the tissues by the capillaries. For instance, Rous and his colleagues (Rous, Gilding and Smith 1930, Smith and Rous 1931*a, b*, Rous and Smith 1931) showed that certain dyes passed directly into the venous portion of a capillary loop. Cobra venom, of molecular weight 5,000, is absorbed directly into the blood stream, but diphtheria and tetanus toxins, of molecular weights greater than 50,000, are not (Barnes and Trueta 1941). Serum proteins do not pass directly into the blood stream from the tissues (Starling 1895-96). The permeability of the blood capillaries increases greatly with trauma, and under the influence of various noxious substances. It does not appear that the passage into the blood stream of particles of bacterial dimensions is facilitated in these circumstances; though Tuttle and Cannon (1935) obtained some evidence that virulent streptococci passed directly into the blood stream after their introduction into the lung alveoli of dogs. The lymphatics, on the other hand, readily become permeable to large molecules and small particles introduced directly into the intercellular tissue spaces, whether they are, for example, inert particles, red blood cells or bacterial in nature (see, for instance, Cappell 1929, Batchelder, Field and Drinker 1931, McMaster and Hudack 1934, Field and Drinker 1936, Schulz, Warren and Drinker 1938, Barnes and Trueta 1941). We have already noted the speed with which bacteria reach the thoracic duct *via* the lymphatics, from the peritoneal cavity, etc. These facts suggest that in areas which, like the skin and subepithelial tissues of the respiratory and alimentary tracts, are liberally supplied with lymphatics, substantial numbers of the invading bacteria are rapidly carried to the lymph nodes draining the site of invasion.

The Filtering Action of Lymph Nodes.—As Drinker, Field and Ward (1934) showed, hæmolytic streptococci or particles of Indian ink introduced into an afferent lymph channel are to a large extent removed from the lymph during its passage through a lymph node. The filtration appears to depend mainly on the complex ramifications of the channels in the node, and to a lesser extent on the removal of particles by phagocytic cells lining the sinusoids of the node. The filtration, however, is by no means complete. Schulz, Warren and Drinker (1938) instilled virulent Type III pneumococci into the nose of rabbits, and recovered cocci from the vessels draining the superior deep cervical node within one hour of the instillation; non-virulent organisms, on the other hand, did not appear in the efferent lymph. Where lymph has to traverse several nodes in its passage to the thoracic duct filtration may be very efficient. Thus Drinker, Field and Ward (1934)

(4) Incubate, titrate, and read as above.

Suppose the t₅₀ mixed with the 1:500 and 1:10 dilutions of serum gives a skin reaction, but that mixed with the undiluted serum does not. It follows that the undiluted serum contains more than 1/500 unit of antitoxin per ml. but it contains less than 1/50 unit per ml. since it is not neutralized by the 1:10 dilution of serum. By varying the serum dilutions, any fraction of a unit may be determined as indicated in the accompanying table.

DILUTIONS OF PATIENT'S SERUM FOR TITRATION OF ANTITOXIN AT 1/500TH LEVEL.

Patient's Serum (ml.)	Saline (ml.)	Dilution	Amount Mixed with 1 ml. of Toxin Dilution (ml.)	Fraction of Antitoxin Unit Tested for
1.0	0	0	1	1/500
0.5	0.5	1 in 2	1	1/250
0.2	0.8	1 in 5	1	1/100
0.1	0.9	1 in 10	1	1/50
0.1	1.6	1 in 16.6	1	1/30
0.1	2.4	1 in 25	1	1/20
0.1	4.9	1 in 50	1	1/10
0.1	9.9	1 in 100	1	1/5
0.1	49.9	1 in 500	1	1/1

The Precipitin Reaction. The precipitin reaction is the specific formation of a precipitate when a soluble antigen and its homologous antiserum are mixed. It is used for the identification of soluble antigens of bacterial extracts, such as pneumococcus polysaccharide, the polysaccharide and protein antigens of the streptococci, etc., and is used for the immunological typing of a number of kinds of bacteria. It is also used for the identification of other protein antigens as, for instance, the identification of bloodstains in forensic medicine.

In the precipitin test antiserum is used undiluted, or in very low dilution which avoids undesirable cross reactions, and is admixed with successive dilutions of the antigen. The titer of the antiserum is expressed as the highest dilution of antigen with which precipitation occurs. It is one of the most delicate and sensitive of the serological reactions, antisera which will precipitate an antigen such as pneumococcus polysaccharide in dilutions as low as 1:100,000 are frequently used.

For the Wassermann test, 10 test tubes, each of which contains 0.5 ml. of saline solution.

- (b) To the first tube add 0.5 ml. of the antigen solution, mix well by blowing in and out of the pipette several times, and transfer 0.5 ml. of this dilution to the second tube. The procedure is repeated until the expected titer, of the antigen, is reached. If the original antigen dilution is 1:2, 1:4, 1:8, etc., but it is more convenient to prepare a 1:100 dilution of the original antigen to begin with, thus giving dilutions of 1:100, 1:200, 1:400, up to 1:25,600, etc.

(2) **Procedure of the Test**

- (a) Distribute the antiserum in amounts of 0.1 ml. in a series of 5 x 50 mm. test tubes, as many as the dilution range to be observed requires.

the capillary walls made permeable by leukotaxine come phagocytes, and an exudate containing antibodies, other antibacterial substances and fibrinogen. The coagulation of the fibrinogen in this exudate leads to the deposition of a fibrin meshwork in the intercellular spaces of the injured tissues. The protein content of lymph will rise, since under the influence of leukotaxine the lymphatic endothelium will have become permeable to the exuded proteins, and under the toxic action of the invading bacteria the lymph will clot in the lymphatic channels. In favourable circumstances, therefore, the intercellular dissemination of the infective material will be hindered by the fibrin deposit in the tissues, and dissemination along the lymph channels by the intralymphatic clots. This clotting process constitutes Menkin's "lymphatic blockade" whereby irritant material is fixed and held at the site of inflammation. If the irritant is sufficiently strong, "fixation" may even precede the diapedesis of leucocytes. According to Menkin, bacteria like *Staph. aureus* stimulate the early formation of a lymphatic blockade, and hence tend to be confined in local abscesses; *Str. pyogenes*, on the other hand, induces a late fixation reaction, and is conspicuously invasive.

The presence of leukotaxine-like polypeptides in the breakdown products of tissue proteins has been demonstrated by Duthie and Chain (1939), and many of the experimental phenomena upon which Menkin bases his hypothesis of inflammatory fixation have been reproduced by other workers, though neither Steinberg and Dietz (1938) nor Lurie (1939) could find any constant association between pH and the predominating type of phagocyte in inflammatory processes. It is probable that a number of factors, including the type of parasite, determine the cellular response, even in the early stages of infective inflammation (see, for example, Gins, Kroemer and Link 1938).

We are chiefly concerned here with the hypothesis of the lymphatic blockade as a defence against bacterial invasion. The chief objection to the hypothesis is the difficulty of demonstrating fibrin deposits and lymphatic thrombi at the periphery of inflamed regions, that is, in the region where they are likely to be effective as a barrier against the spread of infection. Rich (1936) points out that acute inflammatory processes induce an increased, not a decreased, flow of lymph from the injured part (see Field, Drinker and White 1932, Hudack and McMaster 1933), and suggests that foreign substances, including bacteria, are "fixed" in inflamed areas by adsorption to proteins, and by precipitation or other physico-chemical change in the lesion (see also Blalock and Burwell 1935-36); and the work of Miller (1938) on the adsorption of a variety of substances, including bacterial suspensions, from regions of inflammation in rabbits, makes it clear that absorption depends largely on the nature of the substance absorbed. Miles and Miles (1943) attribute the apparent fixation of substances in the inflammatory lesion to an accumulation of exudate in the tissues to such a degree that the existing lymphatic system can drain away only a small fraction during the period of experimental observation, with the result that any foreign material diluted in the exudate appears also to pass slowly from the lesion. Local deposits of fibrin may perhaps improve antibacterial defences in another way. M. R. Smith and Wood (1949) observed that little phagocytosis of pneumococci by leucocytes occurred in citrated rat plasma, but when fibrin strands were produced in the mixture by addition of thrombin, the leucocytes could move on the solid surface of the strands, and pin the cocci against them as a preliminary to a highly effective phagocytosis.

We should at this point emphasize that the term "fixation" is also used for two phenomena that are distinct from the fixation discussed above. The first concerns the

PROTOCOL FOR THE PRECIPITIN TITRATION

Tube Number	Antiserum (ml)	Antigen	
		Dilution	Amount (ml)
1	0.1	1:100	0.1
2	0.1	1:200	0.1
3	0.1	1:400	0.1
4	0.1	1:800	0.1
5	0.1	1:1600	0.1
6	0.1	1:3200	0.1
7	0.1	1:6400	0.1
8	0.1	1:12,800	0.1
9	0.1	1:25,600	0.1
antiserum control	0.1	saline solution	0.1
antigen control	saline solution 0.1	undiluted antigen	0.1

- Carefully layer 0.1 ml. of the antigen dilutions onto the antiserum, each of the serial dilutions in successive tubes, so that the juncture between the two is clear and sharp.
- Incubate at 37° C. for 2 hours, examining at 30 minute intervals for the formation of precipitate at the juncture of antiserum and antigen. This is the *precipitin ring test*.
- Shake the tubes to thoroughly mix the antiserum and antigen, and store overnight in the refrigerator.
- Next day the precipitate will have settled out and can be read by gentle agitation of the tubes.
- It is essential that controls of antigen plus saline, and antiserum plus saline, be included, and these should show no precipitate.

The precipitin test may also be carried out in capillary tubes to conserve antiserum, and to utilize the relatively small quantities of antigen available in bacterial extracts as in the typing of streptococci.

saline in certain proportions floccules appear, and the antigen is titrated to determine the smallest amount of saline which, when added to 1.0 ml. of antigen, produces aggregates which completely disperse upon the addition of more saline. Syphilitic serum has the property of preventing this dispersion. The test is based on the mixture of constant amounts

saline. A positive reaction is indicated by the presence of floccules in the mixture.

PROTOCOL FOR THE KAHN FLOCCULATION TEST

Tube Number	Antigen (ml)	Serum (ml.)	Serum Antigen Ratio	Shake vigorously for 2 minutes	Saline (ml)
1	0.05	0.15	3:1		0.5
2	0.025	0.15	6:1		0.5
3	0.0125	0.15	12:1		0.5

of a saline suspension, into the open mouth. The animals so treated were killed after intervals varying from a few hours to a month or more, and cultures were prepared from the blood, liver, spleen, mesenteric glands, the small intestine at different levels, and certain other situations. In this way it was possible to follow the spread of infection throughout the body. These observations are of particular interest because they are concerned with a natural disease of mice, and because the portal of entry is that by which the parasite gains access to its host in the natural spread of the disease.

It would seem that the bacilli, when they gain access to the body by the mouth, fail to establish any immediate foothold in the intestine, and for the most part rapidly succumb. A certain number, however, enter the tissues from the alimentary tract and are carried to the mesenteric lymph glands. Later they enter the blood stream, probably via the thoracic duct, but are rapidly removed from the circulation by the reticulo-endothelial cells, particularly those of the liver and the spleen. During this phase the blood taken from the heart is sterile, and *Salm. typhi-murium* cannot usually be recovered from the intestine; but the liver, spleen and mesenteric glands show its presence in increasing numbers. In many animals this stage is followed by a secondary bacteræmia, which increases in intensity until the animal succumbs. The intestine, which as stated above is rapidly freed from the invading bacteria during the primary stage of the infection, becomes secondarily infected during its later stages, probably by way of the bile-duct.

A similar series of experiments were carried out using *Salm. paratyphi B* as the infecting agent—an organism closely related to *Salm. typhi-murium*, but far less pathogenic for the mouse. The same rapid disappearance from the intestine was noted, and the same localization in the lymphatic glands; but in this case there appeared to be no tendency for the infection to spread beyond this primary focus, though the bacilli might persist in the mesenteric glands for weeks or months. A relatively avirulent variant of *Salm. typhi-murium* behaved in the same way as *Salm. paratyphi B*. These observations were extended by Maaloe (1948), who showed that a virulent strain of *Salm. typhi-murium* and an avirulent but nevertheless equally "endotoxic" variant were equally invasive, both reaching the mesenteric lymph nodes; but that the avirulent variant was destroyed there. Virulence was associated with *in vitro* resistance to the bactericidal action of fresh complement-containing serum.

The Antibacterial Action of Complement and other Humoral Substances.

Little is known about the *in vivo* importance of the bactericidal and bacteriolytic effects mediated by complement. Though purely humoral effects of this kind are probably less important than was at one time supposed, they are certainly operative with some organisms.

Thus, apart from Pfeiffer's classical experiments with *V. cholera*, Buxton and Torrey (1906d) note that many of the typhoid bacilli that collect on the surface of the omentum after an intraperitoneal inoculation are destroyed by extracellular lysis instead of being ingested by macrophages, and many workers have recorded analogous observations. We have just noted an example of an association of virulence and susceptibility to complement in *Salm. typhi-murium*, and there are other instances of this among Gram-negative bacteria. Moreover, in an experimental leptospiral infection of rodents, Stavitsky (1945) observed very little localization at the primary lodgment, and no evidence, either *in vitro* or *in vivo*, of phagocytosis of the organisms; he concluded that they were ultimately destroyed by lytic antibody. With Gram-positive organisms, like pneumococci or streptococci, it would seem, however, that this purely humoral mechanism plays no part. Besides complement, other humoral substances, either present in the tissue, or induced as the result of infection, have been reported as significant, or potentially significant, in antibacterial defences. These we consider in Chapter 52.

Agglutination. Bacteria, and other particulate antigens, aggregate in clumps in the presence of homologous antiserum, and are said to be agglutinated. The agglutination reaction is useful in the serological identification of bacteria, especially those of the group of enteric bacilli such as the *Salmonella* and dysentery bacilli. It is also the immunological reaction made use of, in conjunction with agglutinin absorption, in the antigenic analysis of bacteria.

The agglutination reaction differs from the precipitin reaction in that the antiserum rather than the antigen is diluted, and the antibody titer of the antiserum is expressed as the highest dilution in which a constant amount of bacterial antigen is agglutinated. Agglutinating antisera commonly show titers ranging from 1:1000 to 1:10,000, and occasionally may reach titers as high as 1:50,000 to 1:100,000 though this is rare. The agglutination of bacteria may be observed either microscopically or macroscopically, the former is generally used for typing purposes and the latter in the titration of antibody.

The Microscopic Agglutination Test. In the microscopic agglutination test either only a few, e.g., two or three, dilutions of antiserum are used, or, more commonly, a single dilution is used which preliminary titration has indicated will produce a rapid and com-

single rapid
right inocu
lating wire add a small amount of bacterial growth. The suspension should be faintly turbid and when this point is reached, the needle is flamed and then used

(2)

(3)

original dilution.

(4) Mount the cover slip on a hollow ground slide with petroleum jelly as in making a hanging drop preparation. No special incubation is necessary, and in a few minutes to an hour at room temperature agglutination occurs.

(5) The preparation may be examined under the low power objective for a curdled appearance, or under high power or oil immersion objectives for direct observation of the agglutinated bacteria. False clumping may occur and is distinguished from true agglutination in that in the latter all of the bacteria are gathered in large clumps with none about the edges of the drop, but false clumping occurs in small aggregates about foreign particles and around the edge of the drop

Macroscopic Agglutination. The titration of agglutinin is carried out in a manner similar to the titration of precipitin except, as noted above, with varying amounts of serum in the presence of a constant amount of antigen.

(1) PREPARATION OF ANTIGEN

- (a) Inoculate an agar slant culture with the bacteria to be used as antigen, spreading the inoculum over the entire surface of the slant.
- (b) After 18 hours' incubation run about 2 ml. of saline solution on the agar slant culture. The saline may contain 0.5 per cent formalin if a formalinized antigen is to be used.
- (c) Rub up the bacterial growth with an inoculating needle or loop to give a uniform suspension of the bacteria in the saline.
- (d) With flamed forceps remove a small piece of cotton from the bottom (sterile) part of the cotton plug of the culture tube and drop it into the saline suspension.
- (e) With a sterile pipette push the piece of cotton to the bottom of the saline, taking care to leave the cotton over the pipette opening.
- (f) Draw up the bacterial suspension into the pipette through the cotton, which serves to filter out coarse particles, and add this suspension slowly to the proper

slightly virulent, strain of the same bacterial species. Without any attempt to recapitulate in detail, we may quote a few illustrative examples.

Wright (1927) studied the response, to the intravenous injection of virulent pneumococci, of rabbits that had been immunized by the injection, at various intervals before the test inoculation, of a killed culture of the same strain. Table 69 and Fig. 245 show the results obtained in two rabbits that had been immunized 3 months previously, and in two normal controls injected with the same dose of the same living culture. Comparison with Table 68 and Fig. 244 will show that the immunized rabbits dealt with the highly virulent culture in the same way as the normal rabbit dealt with the slightly virulent strain.

TABLE 69

SHOWING THE NUMBER OF PNEUMOCOCCI PER ML. OF CIRCULATING BLOOD AT VARIOUS TIMES AFTER INOCULATION OF A VIRULENT STRAIN INTO NORMAL AND INTO ACTIVELY IMMUNIZED RABBITS.

Time after Injection	Normal		Immunized.	
	Rabbit 247.	Rabbit 248.	Rabbit 299.	Rabbit 300.
Immediately	870,000	1,100,000	1,000,000	1,000,000
5 hours	1,300	3,300	12	68
24 "	142,000	1,953,000	0	289
48 "	2,800	Innumerable	149	70
96 "	Dead	Dead	0	0

The phagocytic reactions that we have described are illustrated in Figs. 246, 247A, 247n and 248, for which we are indebted to the late Professor H. D. Wright.

The reaction in the lung capillaries in these immunized animals is illustrated by the following figures (Wright 1927) obtained from a film preparation.

Total number of pneumococci seen	893
Phagocytosed by polymorphonuclear cells	297
Phagocytosed by mononuclear cells	340
Total phagocytosed	637
Total outside phagocytes	256
In unphagocytosed aggregates associated with platelets	206
In free aggregates	53

Kerby, Holland and Martin (1950) measured the rate of removal of *Bact. friedlanderi* slowly infused into the inferior vena cava. During the first four hours it was, on their scale of measurement, of the order of 40 per cent., and was increased to 70 per cent. or more when the animals had been actively immunized by a similar perfusion 2 weeks previously, or passively immunized with plasma from another immune animal. Specific immunization greatly enhances the capacity of the rabbit to clear the blood of intravenously injected rickettsiae (Bieling 1949).

The results obtained when immunized animals are injected with virulent bacteria by other routes—by intraperitoneal or subcutaneous injection or by the mouth—are in entire conformity with those described above. An immunized animal reacts to a highly virulent bacterium as does a normal animal to one of lower virulence. The exact degree of difference in behaviour depends on the grade of immunity that has been established.

We may cite as further examples illustrating this important generalization about the reactions of normal and immune animals the studies of Angevine (1936) on intradermal infections by virulent streptococci; those of Jawetz and Meyer (1944a, b; see also Walker *et al.* 1953) on the reactions of the guinea-pig to infection by plague bacilli; and those of Downs and her colleagues on infections of mice and rats with *Brucella tularensis*

and if thought desirable of the general population, exclusion of contacts from schools, factories and other places of congregation, and careful observation of all doubtful cases of disease. Care should be taken over the treatment of the crusts, since they contain the variola virus, and may easily be disseminated in the form of dust.

Inoculated cutaneously into a fully susceptible human subject, vaccinia virus gives rise, after an incubation period of 3-4 days, to a papule which on the 6th or 7th day becomes vesicular. The vesicle, which is multilocular, umbilicated, and surrounded by a red areola, progresses to the pustular stage between the 10th and 12th days, after which retrogression sets in and the pustule dries up. The crust becomes detached about the 21st day, leaving a red pitted scar—the so-called foveation—which in the course of years turns white. The size of the reaction is dependent on the concentration of virus in the lymph (von Gröer 1935). A rise in temperature may occur about the 4th day, reaching its maximum about the 8th day; there may also be some enlargement and tenderness of the regional lymph nodes. A second inoculation made some years later may be followed by the usual *primary* type of reaction, or it may be accelerated in its evolution, though not in its appearance—*vaccinoid reaction*—the maximum being reached between the 3rd and 7th days. In persons recently vaccinated the so-called *immune reaction* is common; this consists of a papule or shallow vesicle reaching its maximum size in 8-72 hours and disappearing without passing through the pustular stage or leaving a scar.

There is some difference of opinion about the interpretation of the immune reaction. Broom (1947), who inoculated both fresh lymph and lymph inactivated by heating to 65° C. for 30 minutes into the same subjects, found that 110 out of 119 persons giving an immune reaction to the fresh lymph reacted also to the heated lymph. These results suggest that the reaction of immunity is essentially an allergic reaction (see also Mitman 1952). For this reason many workers prefer the term *immediate* to *immune* (Benenson 1950). Even this term is inaccurate, as the immune vaccinal reaction differs from the typical immediate reaction of the wheal-and-erythema type met with, for example, in hay fever. The best term, we think, by which to describe it is the *allergic* reaction. Though this reaction may persist long after immunity has disappeared, it is nevertheless true to say that, provided a lymph of proved activity is used, an allergic reaction does probably mean that the subject possesses a considerable, though by no means necessarily complete, immunity to vaccinia, and inferentially to smallpox. Otherwise it would be difficult to understand why in Broom's series the proportion of primary reactions rose and of immune reactions fell in relation to the length of time elapsing since previous vaccination.

For human vaccination calf or sheep lymph is generally employed, but lymph taken from vaccinal lesions in other animals may be used satisfactorily. Bacterial contamination can be largely controlled by phenol and glycerol (McClellan 1919) or by one of the quaternary ammonium compounds (Ducor 1947). If stored in the dark below 0° C vaccine lymph should retain its potency for at least 6 months; if between 0 and 10° C. for 14 days; if at room temperature (20° C.) for not more than 7 days. Of late years two other types of vaccine have been introduced, partly to provide a bacteria-free product, partly to avoid the severe local and constitutional reactions to which calf lymph sometimes gives rise, and partly in the hope of preparing a vaccine of constant virulence. The first is the so-called Rivers vaccine,

glutination, from + or barely perceptible partial agglutination to ++++ of complete agglutination with a clear supernatant, while others simply record the presence or absence of agglutination with a single + sign. The agglutinin titer of the antiserum is the highest dilution in which definite agglutination occurs.

Complement Fixation. The complement-fixation test is based on the observation that complement, a heat-labile constituent of normal serum, combines with an antigen-antibody complex and is said to be fixed. Since this fixation produces no visible change, a hemolytic system, consisting of sheep erythrocytes and anti-sheep cell hemolysin, is added. If the complement is free, *i.e.*, has not been fixed, and inferentially the original union of antigen and antibody has not occurred, the erythrocyte-hemolysin complex combines with the complement, and visible lysis of the red cells occurs. Conversely, if the erythrocytes are not lysed, the test antigen-antibody system has combined and fixed the complement, leaving none for hemolysis. This complement-fixation test is most often applied in the serodiagnosis of syphilis, but has proved very useful with the rickettsiae. Bacterial antigens fix complement readily.

The following reagents are required:

- (1) The antigen antibody system to be tested, either component of which may be unknown.
- (2) Anti-sheep erythrocyte hemolysin, prepared by the immunization of rabbits with sheep red cells.
- (3) A 2 per cent (by volume of packed cells following centrifugation) suspension of washed sheep erythrocytes in saline.
- (4) A source of complement, practically always fresh guinea pig serum.

Titration of Reagents Since the test is necessarily quantitative with respect to the relative proportions of the various components, the activity of these must be titrated prior to the actual test. These preliminary titrations include.

- (1) The titration of hemolysin which is carried out by varying the amount of hemolysin in the presence of constant amounts of sheep erythrocytes and complement, the last in amounts more than necessary for complete lysis. This titration is carried out as indicated in the accompanying protocol. The smallest amount, *i.e.*, highest dilution, of hemolysin required to bring about complete lysis is the *hemolytic unit*. In the final test 2 units in a volume of 0.5 ml. are used in each tube and on the basis of this titration the hemolysin is diluted to contain 4 units/ml.

PROTOCOL OF HEMOLYSIN TITRATION

Tube Number	Hemolysin Dilution (0.5 ml.)	Complement 1:10 Dilution (ml.)	2% Suspension Erythrocytes (ml.)	Saline (ml.)
1	1:1000	0.3	0.5	1.7
2	1:2000	0.3	0.5	1.7
3	1:3000	0.3	0.5	1.7

control (10)*	none	0.3	0.5	2.2

* both controls must be negative

(3) The greater the area of cicatrix left by the vaccination, the greater is the diminution of the fatality rate (see Table 173).

According to Turner (1905-06), among cases with equal total areas of vaccination scarring there is no difference in the amount of protection afforded by different numbers of scars. Hanna (1913) at Liverpool, who made observations on

TABLE 171

Year.	Vaccinated.			Unvaccinated or Doubtful.

943 vaccinated persons suffering from smallpox, compared the area of scar tissue left by primary vaccination with the severity of the disease. From the information he gives we have worked out the following average figures:

Modified discrete, and discrete	0.728 sq. in.
Profuse discrete, and semi-confluent	0.670 sq. in.
Confluent and death	0.456 sq. in.

These figures support those collected by Cameron and others in showing the inverse relationship between the area of scar tissue and the severity of the disease.

(4) In vaccinated persons the fatality from smallpox increases with the length of time elapsing since vaccination. Table 174 affords a comparison, in this respect, between vaccinated and unvaccinated persons. This table also shows a very different age-grouping of admissions in vaccinated and unvaccinated persons,

PROTOCOL OF COMPLEMENT TITRATION

control (10)*	0.00	2.5	0.0	0.5

* control must be negative

- (2) The complement of fresh guinea pig serum is similarly titrated, using variable amounts of complement in combination with constant amounts of erythrocytes and

ment fixation test 2 full units in a volume of 1.0 ml are used in each tube. The reason for the excess amount is that some complementary activity is lost during the time allowed for fixation, even if no fixation occurs, and the test is sufficiently sensitive even with this slight excess.

- (3) Certain properties of the antigen are pertinent to the test and must also be determined by preliminary titration. These properties include anticomplementary activity, i.e., inhibition of the action of complement, hemolytic activity, and binding power for complement. The titration of these is shown in the accompanying protocol. In general, the binding power of the antigen should be at least 10 times its anticomplementary action, and in the final test not more than one third of the amount of antigen found to be anticomplementary may be used. It is self-evident that the antigen must not lyse red cells in the concentrations used in the test.

Procedure of the Test:

- (1) Inactivate the test serum, i.e., destroy any traces of complement in it, by heating to 56° C. for 15 to 20 minutes, and dilute 1:5, and distribute in three 15 x 100 mm. test tubes as indicated in the accompanying protocol. Bring the total volume in tubes 2 and 3 to 0.5 ml. by adding 0.25 and 0.375 ml. of saline respectively.
- (2) Add 0.5 ml. of antigen, diluted to contain 20 complement fixing units per ml. to each tube.
- (3) Let the mixture stand at room temperature for 10 minutes.
- (4) Add 1.0 ml. of complement, diluted to contain 2 full units per ml., to each tube.
- (5) The mixture may be incubated in a water bath at 37° C. for 1 hour, or stored in the refrigerator overnight and warmed in the water bath for 10 to 15 minutes before proceeding with the test the following day. This time interval is allowed for fixation of the complement by the antigen antibody complex, and the latter method is referred to as "ice box fixation."
- (6) Add 0.5 ml. of hemolysin diluted to contain 4 hemolytic units per ml. to each tube.
- (7) Add 0.5 ml. of a 2 per cent suspension of washed sheep erythrocytes to each tube.
- (8) The appropriate controls of the serum, antigen, hemolytic system and erythrocytic suspension are indicated in the protocol, and must be included.
- (9) Incubate in a water bath at 37° C. for 15 to 60 minutes.
- (10) Read the hemolysis as complete (+++), partial (+++, ++, +, ±) or negative.

after birth to enable the passive immunity received from the mother to wear off (Béclère 1936). (For general discussion of vaccination, see Greenwood 1930, 1935, Report 1931, Russell 1941, Robinson 1941, Stevenson 1944, Downie 1951b)

Complications of Vaccination.—Of the complications that may follow vaccination, suppuration is one of the commonest, and tetanus one of the most serious. Owing to the use of calf lymph, which cannot be satisfactorily sterilized, the introduction of micro-organisms into the wound is inevitable, but it is very difficult to say how often the calf lymph is responsible, and how often uncleanness on the part of the operator, or during the after-treatment. Occasionally, as at Malmo, severe necrotic lesions may occur owing to the presence of pathogenic staphylococci in the lymph (Magnusson 1932, 1933). It may be noted that foot-and-mouth virus has been found occasionally in specimens of calf lymph, though there is no evidence that its presence excited any unfavourable reaction in vaccinated children (see Gildemeister 1931, Gildemeister and Helm 1932*a*, *b*).

Tetanus is a very rare complication; thus in 1904–13 in the United States, 31 million lymph doses were inoculated into human beings, and only 41 cases of tetanus were observed. Infection in these cases may be carried by the lymph; but tetanus occurs only in those cases in which a protective shield or dressing strapped to the arm has been applied. Vaccination insertions treated openly have never been followed by tetanus (Armstrong 1927).

Generalized vaccinia is a serious complication, which is estimated to occur in 1 out of every 30,000 subjects vaccinated. Persons with chronic skin lesions are said to be specially susceptible. The disease varies from a mild rash with a few scattered vesicles and little constitutional disturbance to a severe variola-like disease with tracheitis, general glandular enlargement, widespread affection of the skin, and a rapid course to death. The case fatality is said to be 30–40 per cent. (see Ross 1941)

Another complication, which is very serious, is *post-vaccinal encephalomyelitis*. The first case of this to be studied in detail was by Turnbull in 1912, but it was not till the publication of Turnbull and McIntosh's report in 1926 that serious attention was drawn to the subject. Clinically, after an incubation period of 10–12 days, with a range of 2 to 28, there is a rapid onset followed by an acute course, the symptoms being cerebral rather than spinal (Report 1928*a*). Histologically, the lesions are widely distributed in the grey and white matter of the brain and cord and are characterized particularly by extra-vascular parenchymatous infiltration with large endothelial and glial cells and by perivascular areas of softening or demyelination (McIntosh 1928). The incidence varies in different countries and at different ages (Stuart 1947–8, Conybeare 1948, Greenberg and Appelbaum 1948), but exact figures are difficult to obtain. The figures quoted by different observers range from about 1 in 1,000 to 1 in 100,000 vaccinated persons. The incidence rate is very low in infants under 1 year of age; it reaches its maximum during the school period, and declines again in adult life. On the other hand, the case-fatality rate is usually highest in infants, intermediate in school children, and lowest in adults. The average for all ages is about 50 per cent. Most cases have occurred after late primary vaccination, but sometimes the disease has followed revaccination—usually performed several years after primary vaccination. There seems to be no constant relationship between the severity of the vaccinal reaction and the liability to develop the disease. The best method of preventing this complication is to perform primary vaccination when the infant is about 3 months old,

analysis. There is however no doubt that these viruses are all very alike, and are able to afford almost complete cross-protection between each other (see Borrel 1903, Bosc 1903, de Jong 1917, Zwick 1924, Toyoda 1924, von Wasielewski and Winkler 1925, Ledingham 1926, Findlay 1936).

One interesting property of the pox viruses is their power to give rise in certain hosts—sheep and fowls particularly—to tumours characterized by epitheliomatous proliferation superficially resembling neoplasms.

Cow-pox is a mild disease affecting the teats and udders. In its clinical form it is not very common, though there is reason to believe that the virus often gives rise to subclinical and latent infections. The disease is transmissible to man, and in unvaccinated persons generally runs a more severe course than that characteristic of vaccinia. The contents of the vesicles both in man and animals may be blood-stained. Histologically, strongly acidophilic compact intracytoplasmic inclusion bodies are seen in the epithelial cells differing from those of vaccinia and variola. Minor serological differences can be demonstrated between cow-pox and vaccinia virus, but each protects against the other and against variola (see Downie 1951b).

Sheep-pox, known in France as *la clavelée*, is of some economic importance. It was studied by Borrel in 1903 who noted the occurrence of distinctive cellular bodies in the lesions, and showed that the causative agent was able to pass through coarse Chamberland filters. The virus was cultured by Gins and Kunert (1937) on the chorio-allantoic membrane of the chick embryo.

The disease, which runs an acute febrile course, is characterized by the development of a vesicular eruption, later becoming pustular, on the more exposed parts of the body. Infection can readily be transmitted to normal sheep by inoculation with the serous fluid contained in the loculated vesicles. The case fatality of the natural disease is very low. Post-mortem examination of fatal cases reveals the presence of generalized lesions. The lungs contain multiple, small, dense, spherical nodules, hyaline in appearance with a central opaque spot; they are commonest near the pleural surface. Similar, but less obvious, lesions are also seen in the liver and kidneys. Prophylactic inoculation with a sensitized vaccine is widely practised in France (Bridré and Boquet 1923, 1933). Inoculation with vaccinia virus is said to protect sheep against sheep-pox (Gins and Kunert 1937).

Rabbit-pox was studied by Pearce and her colleagues (Pearce *et al.* 1936a, b, Rosahn *et al.* 1936a, b, Hu *et al.* 1936). The virus is filtrable through Berkefeld V candles; it is antigenically related to the vaccinia virus, but not to Virus III (see p. 2141), or the virus of infectious myxoma (see p. 2243); and it is able to infect guinea-pigs, mice, calves, and probably rats.

Infectious Ectromelia or Mouse-pox is a disease of mice first described by Marchal (1930) at Hampstead. It occurs in an acute form characterized by the presence of visceral lesions, in a chronic form characterized by necrosis of the feet, and in a latent symptomless form. In the chronic form one of the feet becomes swollen and oedematous, and serous fluid escapes from the surface, forming minute scabs. The disease may retrogress, in which case the foot becomes gangrenous and sloughs off leaving healthy tissue behind; or infection may spread to another foot, the tail, or the mouth, and lead to the death of the animal. In the acute form the animals die without any external lesions. *Post mortem* the liver may be dirty grey in colour, or it may be red and mottled due to the presence of small white focal areas of necrosis. The spleen is slightly enlarged, and may show large white areas.

sequence of events may probably be accepted as a prototype for the behaviour of the variola virus (see p. 2112).

Fowl-pox requires separate consideration. According to Doyle (1929) three clinical forms may be recognized: (1) wart-like nodules on the comb, wattles, and skin of the head; (2) adherent, yellow, cheesy membranes in the mouth; (3) a watery or muco-purulent discharge from the eyes and nose; this form is sometimes referred to as "roup." One, or any combination, of these forms, may be present in the same bird.

The fowl-pox virus is said to be brick-shaped and slightly larger than vaccinia virus, measuring about $332 \times 264 \text{ m}\mu$ (Boswell 1947). Though Toyoda (1924) maintained that by passage through rabbits the fowl-pox virus could be converted into the vaccinia virus this seems very doubtful (Findlay 1928). Both in its pathogenicity and in its serological reactions it seems to be less nearly related to vaccinia than are the mammalian pox viruses. In the lesions of fowl-pox so-called Bollinger inclusion bodies, and Borrel elementary bodies, corresponding to the Guarnieri corpuscles and the Paschen bodies of vaccinia, can be found (see Ludford and Findlay 1926).

For protection against the disease pullets may be vaccinated during the first 4 or 5 months of life with virulent fowl-pox virus (see Beaudette 1949). Alternatively the pigeon-pox virus may be used. Doyle and Minett (1927) found that pigeons were resistant to fowl-pox but that fowls were susceptible to pigeon-pox. They obtained evidence moreover that pigeon-pox protected fowls against fowl-pox. The vaccine is prepared with dried pigeon-pox crusts suspended in glycerolated saline. The advantage of this vaccine is that it can be used at any time of life.

Kikuth and Gollub (1932) described a disease of canaries, which appears to be **canary-pox**. It was studied by Burnet (1933) and Burnet and Lush (1936a), who found that the clinico-pathological picture differs from that of fowl-pox, but that the viruses of the two diseases are antigenically closely related.

CONTAGIOUS PUSTULAR DERMATITIS OF SHEEP

Contagious pustular dermatitis or Orf (from a Saxon word for cattle) is a highly infectious disease of sheep. It occurs not infrequently in this country and Australia, and has been described by several workers on the Continent (for references see Glover 1928). It is probable that natural cases occur also amongst goats. The disease varies in severity: in the mild form there are pustular lesions on the lips and surrounding tissues; in the severe form lesions occur on the oral mucosa, the vulva, the cornea, and on various other parts of the body, particularly the regions of the coronet and the tail. Sheep of any age may be attacked, but the disease is commonest in weaned lambs up to 1 year old. Experimentally vesico-pustular lesions can be produced by scarification of the thighs of normal lambs, or by intradermal inoculation of the lip with a suspension of dried crusts from the natural lesions; the crusts generally prove active in a dilution of 1/50,000. Elementary bodies may be found in the vesicular fluid (Lloyd *et al.* 1951). The disease is not readily transmissible to laboratory animals, but some strains can be adapted to the rabbit, in which they produce a papillomatous form of lesion (Selbie 1944). The causative virus is of much the same size as that of vaccinia, by the centrifugal method it appears to be at least $150 \text{ m}\mu$ in diameter (Selbie 1945). It withstands

MORPHOLOGY, CELL STRUCTURE, GROWTH AND CHEMICAL COMPOSITION OF BACTERIA

Bacteria are widely distributed over the surface of the earth—in the soil, in the sea and in fresh water, and on the bodies of plants and animals. The true bacteria constitute only a portion, though a very large portion, of this vast microbial population, the remainder consisting of unicellular protozoa and fungi, including yeasts, molds and actinomycetes. This microbial population far exceeds, in point of numbers of individuals, that of all macroscopic plants and animals combined. So ubiquitous are the bacteria that there are few places to which man has access where they may not be found. They are present in the upper atmosphere and deep in the earth and sea. With the exception of certain obvious places such as the interior of active volcanoes, they may be said to occur universally over the surface of the earth. The skin of animals is covered with, and their gastro-intestinal tracts contain, tremendous numbers of these organisms. It is often stated that bacteria are absent from the tissues of healthy animals, but it appears that this is not always true.

As the discovery of this microbial world necessarily awaited the development of optical systems which made bacteria visible, so the structure of our knowledge of these organisms is built upon concepts derived from direct observation. Although the morphology of bacteria will not carry us far in their taxonomy, nor will it give us any insight into their physiological activities, nevertheless knowledge of the size and shape of these microorganisms, their internal and external structures, their processes of division and other characteristics determinable by direct observation, is the solid foundation upon which bacteriology rests.

Size. Different kinds of bacteria vary considerably in size. They are ordinarily measured in terms of microns (μ). The micron, a unit of the metric system, is 0.001 millimeter or roughly 1/25,000 of an inch. The average bacterium of rod shape measures about 2 μ in length and 0.5 μ in diameter. One large spherical bacterium has been described that measures about 2 μ in diameter; the most common microbe found in suppurative processes is a spherical bacterium about 0.8 μ in diameter. The largest bacteria belong, as a rule, to the group of spirally twisted or screw-shaped forms¹; one of these² has been found to measure as much as 35 μ in diameter. Perhaps the largest pathogenic bacterium is the spirochete of relapsing fever, which may measure

¹ A bacillus (*B. butschlii*), however, studied by Schaudinn (Arch. f. Protistenk., 1902, 1:306) measures from 50 to 60 μ in length and from 4 to 5 μ in width.

² *Spirillum colossus* (Centralbl. f. Bakt., 1902, Abt. II, 9 608).

(Downs *et al.* 1949, Buehler and Downs 1949, Downs and Woodward 1949). It applies not only to clearance from the blood, but also to disappearance of the bacteria from the viscera and the lymphatic system.

The immunity with which we are here concerned is, it should be noted, strictly specific. The influence of non-specific factors on immunity is considered in Chapter 52.

The Passive Transference of Antibacterial Immunity.—The increased resistance that an actively immunized animal enjoys in virtue of the increased efficiency of the defence mechanism considered above can be passively transferred from an immunized to a normal animal by injecting into the second the blood serum of the first.

It follows that we must regard the mechanism by which virulent bacteria are disposed of, when once they have gained access to the tissues of an immunized animal, as an integrated system of cellular reactions conditioned by the presence of specific antibodies in the blood or tissue fluids.

Again, a few examples will suffice.

Bull (1915*a*, *b*) found that, in a rabbit in which a bacteraemia had been established by the intravenous injection of pneumococci, the bacteria were removed from the circulation within about 15 minutes after the intravenous injection of 0.2-0.5 ml. of antipneumococcus serum per kilo-body-weight of the rabbit.

Wright (1927) showed that the clearing mechanism of a normal rabbit could be rendered highly effective against virulent pneumococci by the intravenous injection of the serum of an actively immunized animal. The results of one such experiment are set out in Table 70 and Fig. 249. The two passively immunized rabbits each received 1 ml. of the serum of an actively immunized rabbit 1 hour before the test dose of culture. It will be noted that the normal animal died between the 5th and 24th hours, so that the expected secondary rise in the number of bacteria was not observed.

TABLE 70

SHOWING THE NUMBERS OF PNEUMOCOCCI PER ML. OF CIRCULATING BLOOD AT VARIOUS TIMES AFTER INOCULATION OF A VIRULENT STRAIN INTO ONE NORMAL AND TWO PASSIVELY IMMUNIZED RABBITS.

Time after Injection.	Normal	Pass. Imm. 1.	Pass. Imm. 2.
Immediately	2,300,000	2,300,000	2,000,000
5 hours	43,000	2	52
24 "	Dead	8	14
48 "	—	0	1
96 "	—	0	0

Manwaring and Coe (1914) perfused a normal liver with a dilute suspension of pneumococci, with and without the addition of an antipneumococcal serum, and found that the retention of pneumococci within the liver capillaries was pronounced in the former cases but very slight in the latter.

There are many earlier observations of an analogous kind.

Bordet (1897) showed that an antistreptococcal serum would protect a guinea-pig against the intraperitoneal injection of a lethal dose of living streptococci. By withdrawing samples of the peritoneal exudate at various intervals after the inoculation, he was able to show that the recovery of the passively immunized animal was associated with a greatly increased degree of phagocytosis, mainly by the polymorphonuclear cells. By a very ingenious experiment he demonstrated that the relatively slight degree of phagocytosis in the peritoneal exudate of the normal animal could not be ascribed to an absence of activity on the part of the leucocytes. If a suspension of *Proteus* bacilli was injected

up to $40\ \mu$ in length. One of the smallest of the well-known pathogenic forms is the so-called "influenza bacillus," which is about $0.5\ \mu$ by $0.2\ \mu$.

Not only does the size of bacteria vary considerably from species to species but there is also great variability within a single species—much greater than one finds among many other forms of life. The bacillus of typhoid fever is found to range from 1 to $3\ \mu$ in length even when the descendants of a single cell, living under substantially identical conditions, are examined.

There is reason to suppose that still smaller organisms may exist. The infective agents of smallpox, infantile paralysis and a number of other diseases cannot be seen with the ordinary microscope and are so small that they will pass through filters that remove all known visible bacteria. These infective agents—known as the viruses or filterable viruses—are believed by many to be minute living organisms incapable of multiplication except in the presence of living host cells. It is open to question as to whether the viruses are related to ordinary bacteria. Measurements made by means of filtration through graded collodion membranes, which allow particles of known size to pass, indicate that the particles of certain viruses are as small as $0.01\ \mu$ in diameter.³

The mitochondria of living cells have been supposed by some investigators to be symbiotic bacteria, visible forms which are parasitic on the host cell as the viruses apparently are. However, microchemical and physical differences between bacteria and such structures render such a supposition unlikely.⁴

Morphology. For practical purposes the morphology of bacteria is best considered under two heads: the morphology of individual cells and groups of cells, or microscopic morphology, and the morphology of large aggregates of cells in bacterial colonies, macroscopic or colonial morphology. The individual cells differ in size, shape and other structural details, features which can be determined only by the use of high magnification. Colonies or masses of cells that develop on the surface of solid media often present peculiarities of form, color, consistency and the like which are apparent upon examination with the naked eye or low power lenses. As will appear, there is a relation between colonial and cellular morphology. Analogous differences may be observed between masses of larger objects which are associated with the appearance of the single objects. A grove of oak trees viewed from a distance too great to permit identification of the individual trees will still appear unlike a grove of pine trees.

Shape. With respect to shape, bacteria exist in three principal types: the spherical or coccus form; the rod-shaped form known as the bacterium or bacillus, and the spiral forms, the various subtypes of which are designated as vibrio, spirillum and spirochete.

Coccus. The cocci may be subdivided on the basis of the positions which the individual cells tend to take with respect to one another. Such groupings are primarily a result of the planes in which cell division takes place and the behavior of the daughter cells after division is complete. Those organisms which separate completely after cell division and appear singly and scattered at random over the microscopic field are designated as *micrococci*. In some

³ The millimicron ($m\mu$) is often used as the unit for such measurements. One μ is equal to 1000 $m\mu$.

⁴ Cowdry and Olitsky. *Jour. Exp. Med.*, 1922, 36: 521.

Buddingh and Dodd (1944) described a form of stomatitis in infants characterized by numerous fine vesicles on the mucosa of the tongue and gums sometimes associated with diarrhoea and caused by a virus differing from that of herpes.

Inoculation of the fluid from a herpes vesicle on to the scarified cornea of a rabbit leads to the development of a severe keratitis, which can be propagated indefinitely by passage. If fluid is taken from an early keratitis in the rabbit, it is possible to produce with it specific lesions in a number of different tissues, such as the skin, buccal mucosa, trachea, liver, adrenal, ovary, salivary glands, brain, and spinal cord (Goodpasture and Teague 1923-24a, Urbain and Schaefer 1927, Smith 1931a). Intracutaneous inoculation of human vesicular fluid produces in the rabbit an insignificant papular eruption, but once it has become adapted to the rabbit's tissues, the virus gives rise to a local herpetic lesion; this method is of considerable value in the titration of infective material. Direct inoculation of human vesicular fluid on to the pad of the guinea-pig's foot is uniformly followed by the development of local vesicular lesions (Bedson 1934). A certain proportion of rabbits inoculated on the cornea develop, after a few days, a fatal encephalitis, characterized by widespread small-celled infiltrations, intense nerve-cell degeneration, and diffuse proliferative changes of some of the fixed elements of the tissue affected (da Fano 1923). Direct intracerebral or subdural inoculation of vesicular fluid into rabbits gives rise to a meningo-encephalitis which proves fatal in about 5 days, and which is transmissible in series to other rabbits by inoculation of the brain suspension.

Rabbit brain is highly infective, but its infectivity can be increased by homogenization—a process which probably acts by disintegration of the cells and liberation of the virus particles in a free form. Freshly homogenized virus may prove fatal on intracerebral inoculation into rabbits in 12-30 hours, and even one ten-millionth of a gram of infected brain tissue may kill the animals within 5 days (Buggs and Green 1936).

Experiments with monkeys have not given uniform results, but according to Teissier, Gastinel and Reilly (1925) cutaneous inoculation in *Callithrix* may result in the development of vesico-pustules, though often merely small papules appear. Corneal or intracerebral inoculations were without effect.

The virus can be passed from rabbits to mice by intracerebral inoculation with the brain of a rabbit suffering from herpes encephalitis, or with the ground-up nictitating membrane of a rabbit in which the corneal reaction is well established (Steigman and Scott 1942). Encephalitis develops in 3-10 days. Infection can be maintained indefinitely by passage through mice (Andervont 1929). With a neurotropic strain, cutaneous inoculation or intranasal infection of mice gives rise to encephalitis (Gildemeister and Ahlfeld 1936, Berry and Slavin 1943, Slavin and Berry 1943).

The herpes virus can be grown easily in tissue cultures, one of the most suitable media being rabbit testis (Parker and Nye 1925b, Gildemeister *et al.* 1929, Smith 1931b). It can also be adapted to grow on the chorio-allantoic membrane of the developing chick embryo. Since pocks are formed on the membrane, this method lends itself to the titration of virus and of neutralizing antiserum (Burnet 1936, Burnet and Lush 1939a, Shaffer and Enders 1939). In the vesicular fluid the virus is present in the form of elementary bodies, which can be stained by suitable means (Taniguchi *et al.* 1934). Examination of the corneal lesions in rabbits during the first 24 hours reveals the presence of large numbers of acidophilic intranuclear inclusion bodies—referred to as "α-bodies" by Lipschütz (1921) (Fig. 302).

species, however, there is a tendency for the individual cells to remain in pairs, and one may observe such pairs intermingled with individual cells. These organisms are called *diplococci*. When this pairing tendency is marked as, for example, in the gonococcus, the individual cells may not be perfectly spherical but exhibit a coffee bean shape with the concave sides facing each other. Often coccus forms tend to remain together in sheets or irregular clusters resembling bunches of grapes. Those which assume this grouping are termed *staphylococci*. Division in two or three planes is, of course, necessary to the formation of such groups. Other coccus forms divide in only one plane but tend to remain together, the result being a chain of cocci. Organisms forming such chains are

Fig. 2. Electron micrograph of *Streptococcus pyogenes*. Note the manner in which the individual cells remain attached to one another following fission, and the tendency of the chains to be made up of attached pairs of cells. (SAB No. 71.)

called *streptococci*. Still other cocci divide in three planes and remain together to form cubical packets of eight cells. These organisms are the *sarcinae*. Not all the cells in a given microscopic field will appear in characteristic groups. Many organisms may be found singly, presumably those which have broken away from the parent group. Chain formation by streptococci is influenced by the medium upon which the organisms have been grown. The acid-producing streptococci of milk, for example, show long chains in milk culture but when grown in nutrient broth may show only a few short chains. In smears of pus or similar material, however, the coccus forms are usually found in their characteristic groupings. Of the coccus forms having definite grouping, the staphylococci are the most consistently characteristic under the microscope.

Bacillus. The morphology of individual rod-shaped bacteria differs considerably from species to species. Not only is there variation in size but the shape of the individual cells differs. Some bacilli have sides more or less parallel with one another but rounded ends. Others have quite square ends which

and Burnet and Williams (1939), working in Melbourne, found neutralizing antibodies present in over 90 per cent. of children and adults of the hospital classes, but in only about 50 per cent. of members of the higher social classes. This they explain by the greater frequency of primary herpetic stomatitis in early life among children of the lower classes. Since recurrent herpes affects persons whose blood serum contains neutralizing antibodies, it is assumed that the virus persists in the body tissues—probably in the mouth (Scott and Steigman 1941)—and that immunity is to a considerable extent non-specific. The failure of the antibody to afford protection is curious. Herpes febrilis constitutes, in fact, one of the most striking exceptions to the general rule that filtrable virus infections usually leave behind them a solid and lasting immunity. A skin reaction that is said to be positive in persons subject to recurrent attacks of herpes was described by Nagler (1944).

Keratitis herpetica of human beings was shown by Grüter in 1912-14 to be transmissible to rabbits by inoculation of the scarified cornea. This observation was confirmed by Luger and Lauda (1921), who found, histologically, alterations in cellular structure similar to those in herpes febrilis. These consisted of giant-cell formation, the characteristic ballooning degeneration of Unna, and bodies which they considered to be due to a specific degenerative reaction of the nucleus, but which Lipschütz regarded as inclusion bodies.

Herpes genitalis has likewise been shown to be transmissible to rabbits, but the keratitis set up by the genitalis virus is much less severe than that set up by the febrilis virus. Similarly, on subdural inoculation the genitalis virus is less virulent; by this route the febrilis virus uniformly produces encephalitis in rabbits, fatal in 4 to 6 days; the genitalis virus does not uniformly produce encephalitis, and, when it does, the rabbits do not die for 5 to 17 days (Blanc and Caminopetros 1924). Lipschütz (1921) succeeded in transferring genital herpes to human beings. Both in the human lesions and in the rabbit's cornea, he found nuclear inclusion bodies of the so-called β -type present in large numbers; they are best looked for in the rabbit's cornea on the 3rd day after inoculation. He was unable to produce immunity to the genitalis virus by inoculation of the rabbit's cornea with the febrilis virus. He therefore regarded the two viruses as distinct.

Herpes zoster.

Herpes zoster differs clinically from herpes febrilis in forming large vesicles or bullæ, in occurring on the trunk, in being almost always unilateral, in being accompanied by sharp neuralgic pains, in being distributed along the course of sensory nerves, and in being non-recurrent. Experiments made to ascertain whether zoster is transmissible to animals have given most conflicting results.

Lipschütz (1921) claimed to have produced keratitis in rabbits with material from 3 out of 7 cases of zoster. Both in human lesions and in the rabbit's cornea, he found acidophilic nuclear inclusion bodies, which he called "zoster bodies." In the rabbit's cornea these bodies were present in greatest numbers on the 4th day after inoculation. The keratitis, when it did develop, was mild, and consisted of small round vesicles, which did not appear till the 4th day, and which after a few days tended to regress. Kundratitz (1924-25) claimed to have transmitted zoster to infants; in contradistinction to herpes febrilis, in which the incubation period of the experimental human disease is only 24 to 48 hours, the incubation period in zoster was 12 to 15 days. Teague and Goodpasture (1923-24) obtained some evidence that the zoster virus differed from that of herpes febrilis mainly in its degree of virulence, but their experiments were not very satisfactory.

appear to have been cut off sharply. Still others assume a highly elongated but oval shape. These last, when short and thick, are often called *coccobacilli*. A given shape is relatively constant within a species although the length-width ratio may vary considerably. The groupings which the cells may assume are a result of post-fission movements, for the plane of division varies rarely if at all. The tendency to remain attached, end to end, resulting in the formation of a chain of *streptobacilli*, is more or less constant for some species but is observed only occasionally in many species. Other groupings of these cells result from the movements of the bacilli after division is complete. Some tend to slide together side by side, a movement known as *slipping*, which results in the formation of palisade-like groups of cells. Still others, in a movement

Fig. 3. Electron micrographs of gold-shadow-cast preparations of *Bacillus subtilis* and *Staphylococcus aureus*. The shadow cast preparation illustrates particularly well the occurrence of staphylococci in clusters of attached cells. The cap at the ends of the bacillus and a single flagellum are shown (Lilly Research Laboratories.)

known as *snapping*, bend sharply at the point of division to an acute angle and present a V-shaped appearance. When this type of movement is associated with a tendency for the bacilli to remain attached end to end, chains of organisms resembling a split rail fence may result. Such snapping often results in breakage of a chain of organisms, the parts of which continue to grow in the new direction. The groupings assumed by bacilli are, however, not as characteristic as those of the cocci.

The Spiral Forms. The third principal type of bacterial form commonly observed is that of the spiral or screw-shaped forms. There are a variety of these which may be distinguished morphologically, but at the moment only three main subtypes may be considered. The first of these is the *vibrio* or curved rod. Smears of such organisms often show chains which, since the organisms curve in alternate directions, suggest a spiral organism. It is not difficult, however, to distinguish between such chains and the truly spiral

subsequent observations leave little doubt that they were working, not with varicella virus, but with the so-called Virus III (see p. 2141). On the other hand, the presence of acidophilic intranuclear inclusion bodies in the testicles of vervet monkeys inoculated with material from human chicken-pox lesions was probably the result of infection with the true varicella virus (Rivers 1926, 1927).

Amies (1933) described a specific agglutination reaction, using as antigen a 0.25 per cent. formalized suspension of elementary bodies prepared by the differential centrifugation of human vesicular fluid. Of 55 sera taken from patients 2-12 days after the onset of the attack, 35 contained agglutinins in a titre of 1/4-1/256, and 20 gave negative results. Antibodies appear about 5 days after the onset, and persist for some considerable time. Convalescent serum has apparently no prophylactic value (Lewis *et al.* 1937).

Relation between Herpes zoster and Varicella.

A large body of clinical evidence has been produced suggesting that zoster and varicella are closely allied diseases. The experimental evidence in favour of this conception has been summarized by Lipschütz and Kundratitz (1925) as follows: (1) In infants inoculated with zoster material, apart from the local vesicles that develop, a general varicella-like eruption may occur; (2) children brought into contact with infants inoculated with zoster may develop chicken-pox; (3) inoculation experiments with zoster, made on children who have recovered from varicella, prove negative; (4) inoculation experiments with varicella, in children who have recovered from natural or experimental zoster, prove negative; (5) the serum from patients convalescing from zoster has a protective action against varicella; (6) both varicella and experimental zoster have the same incubation period; (7) similar cytological appearances are found in both diseases.

On the other hand, there are many differences (Barrett 1938). For example, zoster is only slightly contagious: chicken-pox is highly contagious. A leucopenia with a relative mononucleosis is the rule in chicken-pox, but not in zoster. Chicken-pox affords almost complete immunity against chicken-pox, but not against zoster. Zoster affords almost complete immunity against zoster, but not against chicken-pox. Chicken-pox is much commoner in zoster contacts than zoster is in chicken-pox contacts. Zoster occurs as often in persons with, as without, a history of chicken-pox (see Seiler 1949).

The close relationship of the two diseases to each other is supported by the observations of Netter and Urbain (1924, 1926, 1931), who found apparently identical antibodies, demonstrable by the complement-fixation test, in the serum of patients with zoster and varicella. Brain (1933), moreover, obtained equally good fixation with zoster and with varicella vesicular fluids. It has further been shown that serum from convalescent zoster patients often agglutinates a suspension of varicella elementary bodies, though to a rather lower titre than a suspension of zoster elementary bodies. On the other hand, Hasskó, Vámos and Thoroczky (1938) never obtained complete cross-fixation of complement between varicella and zoster sera; and in a high proportion of sera no cross-fixation occurred at all. As already noted, Goodpasture and Anderson (1944) were able to cultivate the zoster virus on pieces of human skin that had been grafted on to the chorio-allantois of the developing chick embryo, but failed to grow the chicken-pox virus under these conditions. The evidence, on the whole, suggests that the two diseases are caused by viruses that are closely related to each other, and possibly even

organisms. A spiral organism which is rigid, or relatively so, is called a *spirillum*, while similar organisms which are flexible are termed *spirochetes*. Further distinctions, such as the presence or absence of an undulating membrane, etc., which are made use of in formal taxonomic schemes, need not concern us here (see p. 728).

Involution Forms. Although the vast majority of bacteria exhibit a marked constancy of form during the early stages of the growth of a culture, in older cultures aberrant forms such as over-sized cocci, Y-shaped bacillary forms and fimbriated forms may be observed. These forms may be the result of aging and represent varying stages in the dis-

Fig. 4. Electron micrographs of gold-shadow-cast *Bacterium coli* from old cultures. One intact cell is present, and the remainder show the granulation of dead and disintegrating cells. (Lilly Research Laboratories.)

solution of the cell structure. Some workers, however, attach significance to such forms and consider them as indicative of the existence of complex life cycles. Such irregular bizarre forms may often be produced at will by cultivation of bacteria under somewhat adverse conditions of temperature, salt concentration and the like. Morphological variations and their implications are discussed at greater length elsewhere (Chap. 6).

THE STRUCTURE OF BACTERIAL CELLS⁵

The structure of bacterial cells, particularly their finer structure, has been of considerable interest since these organisms were first studied. They are so small, however, that the limitations imposed by the optical system employed become of considerable importance.

⁵ The cytology of bacterial cells is discussed at length by Lewis: *Bact. Rev.*, 1941, 5:181; and by Knaysi: *Elements of Bacterial Cytology*. Comstock Publishing Co., Ithaca, 1944.

endemic, but outbreaks occur from time to time, occasionally reaching epidemic proportions. In the year 1923, for example, 1854 separate outbreaks were reported, necessitating the slaughter of 125,098 animals.

The disease is usually mild, causing a case-fatality rate in cattle of not more than 2-3 per cent., and a slightly higher rate in sheep and pigs; on the Continent, however, a malignant form sometimes occurs, killing 50-70 per cent. of young animals that are attacked. The importance of the disease lies not so much in the deaths to which it gives rise as in the debilitating effect it has on the general health of the animals, leading to a fall in milk and meat production. The incubation period is 2 to 7 days. Infection usually occurs from animal to animal, the infective material coming into contact with the mucosa of the mouth, nose or conjunctiva, or with an abraded skin surface. Cases of direct infection are easy to understand; the real problem lies in explaining the origin of foot-and-mouth disease in animals that have not, so far as can be ascertained, been in contact with infected animals. Numerous explanations have been offered of these cryptogenic cases. Thus it is supposed by some that infection is carried by contaminated hay, straw, milk, drinking water, clothes, and other objects. In support of this, it has been found that the virus may survive on chopped hay at room temperature for at least 15 weeks, and on bran for at least 20 weeks (Report 1927). Moreover, there is evidence that the virus may resist putrefaction for long periods (Report 1928b) and survive in offal (see Henderson and Brooksby 1948). In this way it is possible to understand how infection may lie dormant for months in dried discharges or in carcasses of infected animals. That the virus may not only remain alive, but may keep its virulence under these conditions, was shown by the development of foot-and-mouth disease in a calf fed with hay that had been contaminated 1 month previously with infected saliva, and in pigs fed on crushed bones from the frozen carcasses of infected animals that had been killed several weeks previously (Report 1927).

Another explanation is that the virus is carried by human and animal agencies. Thus it has been suggested: (1) That birds, particularly starlings, may carry infectious material on their feet. For this there is a considerable amount of circumstantial evidence (Bullough 1942, Wilson and Matheson 1952), supported by the fact that large epidemics in England and Wales often coincide with severe disease on the Continent. Direct evidence, however, is lacking, and in the nature of the case would be difficult to secure. (2) That wild rodents may carry the disease and transmit it to cattle, sheep, and pigs coming into contact with them (see Beattie *et al.* 1928). Many of these rodents are susceptible to experimental infection, but practically all experiments designed to test the possibility of natural spread amongst them have given negative results. The virus has, however, been demonstrated in hedgehogs on an infected farm (see McLauchlan and Henderson 1947). Experimentally, it has been found that healthy hedgehogs placed in contact with affected cattle may themselves become infected, and that a healthy cow placed in a stall with infected hedgehogs may develop typical foot-and-mouth disease (Report 1937). (3) That the virus may gain access to, and persist on, the nasopharyngeal mucosa of human beings, who can then act as healthy carriers of the disease; for this there is a certain amount of epidemiological, but no direct experimental evidence (Kling and Hojer 1926). (4) That infected cattle may remain as chronic carriers; it has been found that infective material may persist on the hooves for some time after recovery from the disease, but this appears to be an exceptional occurrence (Gins

The Compound Microscope. With the ordinary microscope objects are viewed by transmitted light and therefore must be sufficiently large to cast a shadow. This size is approximately half the wave length of the light used. The highest numerical aperture that is practical in the objective is 1.4. Such a lens, when used with monochromatic light with a wave length of 5460 Å or 546 m μ , will resolve a particle having a diameter of 0.2 μ . Objects somewhat smaller than this may be seen in that they are visible but are not resolved and neither size nor shape can be determined. Since many bacteria are no wider than 0.2 to 0.5 μ the hope of observing intracellular structures is a faint one. Some workers, Barnard⁶ in particular, have attempted to extend the limits of resolution through the use of ultraviolet light and quartz lenses coupled with "seeing" by means of a photographic plate, but such efforts have not added greatly to knowledge.

The Darkfield or Ultramicroscope. In the instrument known as the darkfield (*Dunkelfeld*) or ultramicroscope, reflected rather than transmitted light is used, objects appearing brilliantly lighted against a black background. The usual microscope may be used as a darkfield by attaching a darkfield condenser in place of the Abbé substage condenser. The principle is the Tyndall effect, perhaps most commonly observed in the appearance of particles of dust in a shaft of sunlight in a darkened room. The limit of resolution is not increased, however, and while exceedingly small objects are visible, they appear only as brilliant points of light. The use of this type of microscope has not contributed materially to knowledge of the structure of the bacterial cell except with regard to the mode of action of flagella. It is, however, very generally used for the detection and observation of very slender microorganisms, especially spirochetes as in exudate from a syphilitic chancre or leptospira in the blood from cases of leptospirosis.

The Electron Microscope.⁷ The recently developed instrument known as the electron microscope operates on a different principle from the optical microscopes in that a stream of electrons is used rather than a beam of light. The electron stream is focused by means of magnetic "lenses," and the interposed object intercepts the stream to cast a "shadow" which is recorded on a photographic plate to give an electron micrograph. Untreated bacteria cast shadows in the electron beam, or the preparation may be "metal shadowed" by the deposition of gold, chromium, etc., at an angle so that the resulting micrograph has a three-dimensional appearance. Remarkable resolution is possible because of the minute size of the electron and sharp photographs may be obtained at magnifications of 30,000 diameters or more. Its application is somewhat limited in that the object must be prepared as a dry film on collodion and observed in a high vacuum, in consequence, living organisms cannot be studied. Application of the electron microscope to biological problems is still in its infancy but has already contributed considerably to knowledge of bacterial cell structure.

Certain structures of bacterial cells are, however, of sufficient magnitude to be seen and studied with the optical microscope. The most obvious of these are structures external to the cell—capsules and flagella.

intramuscular injection of the virus. She found that if one foot was adequately protected from pressure by being wrapped in cotton-wool, no lesions developed on this foot after intramuscular injection, though typical vesicles appeared on the unprotected feet. Moreover, by exposing the feet to unusual pressure, as by keeping the animals in cages with a coarse wire-mesh floor, she was able to induce the formation of vesicles on the toes, and even on the dorsal parts of the feet—situations in which vesicles do not usually occur. The disease can readily be passed from animal to animal by inoculation with infective material. Complement-fixing bodies may be found in the blood serum of convalescent guinea-pigs (see Krag and Schmidt 1937).

Rabbits, rats and mice can all be infected, but the experimental disease is less severe and less typical than in guinea-pigs; dogs and cats sometimes prove susceptible; ducks can be infected by inoculation of the virus into the thickened pads of skin under the toes (Report 1937). Unweaned white mice are highly susceptible to intraperitoneal inoculation, and are even more useful than cattle inoculated into the tongue for the detection of neutralizing antibodies and for revealing antigenic differences between strains belonging to the same type (Skinner *et al.* 1952). The disease practically never spreads from experimentally inoculated to normal rodents. Even highly susceptible cattle placed in contact with infected guinea-pigs rarely contract the disease.

Properties of the Virus.—The virus is present in great concentration in the vesicle fluid of experimentally infected guinea-pigs; even when diluted 1/1,000,000 times it is generally infective for normal guinea-pigs. In the blood, during the febrile stage of the illness, the concentration is less, but even this is active in a 1/1,000 dilution (Report 1927). In cattle during the febrile stage of the disease, the saliva, urine, milk and vesicular fluid are infective; but in 3 to 6 days after the appearance of the lesions they lose their infectivity completely. For diagnostic purposes, it is therefore important to use fresh vesicular material, not more than 2 days old (Olitsky *et al.* 1928). The rapid disappearance of the virus from the local lesion and blood of infected animals is one of the most remarkable features of foot-and-mouth disease; within the space of 3 or 4 days as a rule the virus, from being present in large quantities, is reduced to such an extent that it is no longer demonstrable by experimental methods.

Loeffler and Frosch (1898) in 1897 were the first to show that the foot-and-mouth virus was filtrable. When present in diluted vesicle fluid, it will pass readily through Berkefeld, Chamberland and Seitz filters. The size of the virus is estimated at 8–12 $m\mu$ by Galloway and Elford (1933) using the gradocol membrane technique, at 20–25 $m\mu$ by Elford and Galloway (1937) and Schlesinger and Galloway (1937) using the centrifugal method, and at 40 $m\mu$ by Barnard (1937) using ultra-violet photomicrography. The suggestion that the A, B, and C varieties are not identical in size (see Modrow 1929) finds no support in the observations of Galloway and Elford (1937). The virus was successfully cultivated by Maitland and Maitland (1931) in tissue cultures containing guinea-pig embryo tissue and clotted guinea-pig plasma. Seventeen successive subcultures were observed, and a titre as high as 1/100,000 was obtained (see also Hecke 1930, Striegler 1933, Kôbe and Fertig 1936). More recent methods of culture use foetal calf skin (see Fogedby and Michelsen 1947, Zuloaga 1947), or the mucosa of the bovine tongue (Frenkel 1950, Mace *et al.* 1951). Growth occurs best in a high concentration of oxygen.

The virus is very resistant to certain methods of disinfection, though easily destroyed by others. Thus when vesicle fluid from the guinea-pig is dried rapidly on a glass slide at 37° C., it is often inactivated immediately; but if dried slowly at room temperature, and kept over H_2SO_4 , it survives for 3 to 6 months. When frozen at 30° C. the virus

Capsules. Many bacteria, perhaps potentially all, form a capsule, which apparently originates from the outer layer of the cell membrane; in stained preparations it can sometimes be seen surrounding the cell like a halo. The capsules of bacteria are often one or two times as thick as the diameter of the cell itself and may appear to extend continuously over a chain of organisms or completely surround paired organisms such as diplococci. Cultures of capsulated bacteria are usually slimy and the growth is sticky and viscous. The capsular material is generally polysaccharide in nature, though some bacterial slimes may contain mucin-like proteins. Some of these forms may be a source of considerable annoyance in the sugar refining industries. The presence of a capsule is also associated with the virulence of a variety of pathogenic bacteria. Pneumococci, for example, which have no capsule are relatively avirulent but when capsulated are highly virulent. Anthrax bacilli are almost always found to be capsulated when observed in preparations made from ani-

Fig. 5. Position of flagella on the bacterial cell. A, monotrichous; B, amphitrichous; C, lophotrichous; D, peritrichous.

mal tissues. The capsule appears to function as a bacterial defense against the activity of phagocytic cells of the body. The sheaths of some of the filamentous bacteria may possibly be a capsule in somewhat different form. The colorless sulfur bacteria which derive their energy through the oxidation of hydrogen sulfide to elementary sulfur deposit sulfur granules in their sheaths. Likewise the iron bacteria which oxidize iron from the ferrous to the ferric state deposit ferric hydroxide in the sheaths surrounding them.

Flagella. Many kinds of bacteria are observed to be motile under the conditions in which bacteria are usually studied. Some of those forms in which motion has never been observed may possibly possess the power of locomotion under certain unusual conditions. Independent bacterial motion is a true movement of translation, and is to be distinguished from the oscillating or quivering movement (brownian movement) exhibited by all very minute particles suspended in water or other fluids. Many bacteria are found to be motile when they are examined after removal from certain culture media, but non-motile if they have been grown on other substances. The colon bacillus, for example, is motile when picked from young colonies on gelatin or agar but is frequently non-motile when taken from broth. The rate at which a bacterium moves has been approximately measured. The typhoid bacillus may

of neutralizing the virus *in vitro*; these can be titrated with considerable accuracy on the bovine tongue (Brooksby 1949).

Prophylactically, immunity may be produced by the injection of animals with a weakly virulent virus, given either alone or in combination with immune serum, or by a virus inactivated by suitable means. The practice of using living virus is open to several objections. The vaccine that is now used most extensively was developed by Waldmann and his colleagues (Waldmann and Kobe 1938, Waldmann *et al.* 1941-2) by applying the two principles of formol inactivation introduced by Vallée, Carré and Rinjard (1926) and of adsorption on to aluminium hydroxide used by Schmit-Jensen, Schmidt and Hansen (1936). It is made from the vesicle fluid and epithelium of the tongues of cattle that have been infected with a highly virulent strain of virus. The suspension is treated with 0.05 per cent. formalin for 48 hours at 25° C. The virus is so attenuated that it can be injected into healthy cattle without ill effect, though it is doubtful whether it is completely killed (Mohlmann 1952). This vaccine has now been used on a large scale in Europe, Mexico, and South America. Immunity develops in about 10 days. The high cost of the vaccine may be lowered if unweaned mice can be substituted for cattle as a source of virus (see Skinner *et al.* 1952). Other methods of preparing vaccine have been described, such as that in which the blood of infected cattle is treated with 0.05 per cent. crystal violet for 6-8 days at 37° C. (see Galloway *et al.* 1948), or in which virus grown in tissue culture is used (Henderson and Galloway 1953). Vaccination is restricted as a rule to countries in which the disease is endemic. Though it is often of undoubted value in protecting animals against the clinical manifestations of infection, it has several weaknesses. In the first place the immunity conferred is more or less type-specific. So long as the infecting types of virus are similar to those contained in the vaccine, a reasonable degree of protection may be assured; but if a variant type arises or is introduced, then the disease may spread freely in the vaccinated population (see Fluckiger 1953). Again, by modifying an attack of the disease, vaccination may conceal the presence of infection, with the result that the disease may be widely spread by apparently healthy animals. Other objections are that commercial vaccines vary in potency and recommended dosage; that the different variants of the virus may be imperfectly represented in the vaccine; that inactivation may be insufficient so that the vaccine actually spreads the disease, that not all animals react alike to the same vaccine; and that immunity lasts for only about 6 months. Basset (1953), in a critical review, concludes that a policy of vaccination can never be more than a palliative method of combating the disease.

Methods for dealing with an outbreak of foot-and-mouth disease vary in different countries (see Fluckiger 1953). In Great Britain, the United States, and Scandinavia a rigorous policy of stamping out the disease by slaughter and disinfection is practised. In Germany the system known as Ring-Impfung is officially employed. This consists in isolating the affected farms, and giving all contact animals combined active and passive immunization, using for this purpose living virus and polyvalent hyperimmune serum. The result is a mild attack of the disease, which leaves behind it a more or less lasting immunity. At the same time animals on surrounding farms are given an injection of serum, the effect of which is to afford them some degree of passive immunity for about 10 days. The serum may, however, mask a mild attack, so that the infection of some animals passes unrecognized and may form a starting point for further spread. The whole area is isolated for 2-3 weeks.

travel a distance of 4 mm., or about 2000 times its own length, in one hour, the cholera vibrio may attain a speed of 18 cm. per hour for short distances.

This power of locomotion depends upon the possession of flagella, long, fragile, filamentous, coiled appendages. These organs are contractile and their propelling action is due, not to a lashing motion as once thought, but to a rhythmic contraction which moves helicoidally over the surface, the action being that of a screw rather than an oar.⁸ Flagella are very slender, 20 to 50 $m\mu$ in diameter, and their demonstration with the optical microscope commonly requires staining methods, such as silver impregnation or mordanting, by which staining material is deposited upon them to make them thicker than they actually are. It has been reported, however, that flagella may be observed in the living unstained state in some bacteria, such as the very large spirilla. The origin of flagella has been a matter of some interest and it has been generally

Fig. 6. Flagella of bacteria stained and viewed with the optical microscope. (Stained.)

assumed that they are extensions of the cell wall or protoplast.⁹ Knaysi¹⁰ has shown, by means of electron micrographs, that they originate in the protoplasm of the cell, and the more recent evidence of van Iterson and Robinow, illustrated in Fig. 7, indicates that their origin is in small spherical bodies lying between the cell wall and cytoplasmic membrane. Whether these correspond to the blepharoplasts of flagellated protozoa is not yet clear. It may be noted that the suggestion of Pijper¹¹ that flagella are capsular polysaccharide twisted off in threads by the motion of the cells, and therefore artifacts, has no basis in substantial evidence.

Bacteria differ from one another with respect to the position of the flagella on the cell body. The *monotrichous* organisms have only a single flagellum at one end, the *amphitrichous* bacteria have either a single flagellum or a tuft

(1936). Outbreaks occurred irregularly, but on a generally increasing scale, till in 1939-40 the number of infected premises was 123 and the number of animals on these premises was over 220,000 (White 1940). It is an acute febrile disease, characterized by vesicles on the snout, lips, oral mucosa, tongue, and feet. The vesicles are 2-3 mm. and upwards in diameter. There is often considerable systemic disturbance, the temperature reaching 108° F. The animals suffer from varying degrees of lameness. Growth is seriously interrupted. The case fatality is low except in young sucking pigs, which may die either as the result of cessation of lactation in the nursing sow or of mechanical obstruction to respiration by the vesicles. Animals that recover develop a temporary immunity, which passes off in a few months' time. The disease spreads readily by contact. The incubation period is about 48 hours. Experimental inoculation is successful by the intradermal or intramuscular route. Clinically, the disease cannot be distinguished with certainty from foot-and-mouth disease, and reliance in the first place has to rest on animal inoculation or on the complement-fixation test. As will be seen from Table 176 the virus of vesicular exanthema of swine differs from that of foot-and-mouth disease in being pathogenic to horses, but not to cattle or guinea-pigs

TABLE 176

DIFFERENTIAL SUSCEPTIBILITY OF ANIMALS TO INOCULATION (Traum 1936)

Virus.	Swine	Cattle.	Guinea-pigs	Horses
Foot-and-mouth . . .	+	+	+	-
Vesicular stomatitis . .	+	+	+	+
Vesicular exanthema . .	+	-	-	±

+ = susceptibility. ± = susceptibility less and irregular. - = insusceptibility

The susceptibility of the horse to vesicular exanthema is less than that of cattle, and may perhaps vary with different strains of virus. The British workers (Report 1937) failed in their efforts to infect horses with a strain of Californian origin. The virus is antigenically different from any of the known types of foot-and-mouth virus, and there appears to be no cross-immunization between the two viruses. Three different serological types are recognized. The disease is spread largely by the practice of feeding swine on raw garbage. In control of the disease reliance is placed on strict quarantine measures.

LUMPY SKIN DISEASE OF CATTLE

This disease, sometimes known as pseudo-urticaria, is common among dairy herds in the Cape peninsula of South Africa. It is characterized by transient, nodular lesions in the skin, and enlargement with subsequent necrosis of the superficial lymphatic nodes. The case fatality is low, but the condition and the milk yield falls. Inclusion bodies staining found in the cytoplasm of the epithelial cells (de Kock 1941). Don and Kipps (1949) described a fatal case in a calf using chick embryos presented a change in feather formation. The virus survives in 50 per cent. glycerol.

of flagella at each end; the *lophotrichous* bacteria have a tuft of flagella at one end; and the *peritrichous* have flagella projecting from the whole body of the cell, the sides as well as the ends. Bacteria having no flagella are termed *atrichous*.

Fig 7. Electron micrographs of shadow-cast preparations showing the flagella of *Proteus vulgaris*. The bacteria were grown to the swarming stage on agar, refrigerated at 5° C. for 16 to 20 hours, floated off in 5 per cent formalin and washed twice before mounting on collodion. The preparations are very transparent and flatten completely so that certain of the internal structures are demonstrable by shadowing. The origin of the flagella in small, spherical bodies about 100 m μ in diameter and remarkably uniform in size, situated between the cell wall and cytoplasmic membrane, is clearly shown (From electron micrographs by Woutera van Iterson and C. F. Robinow. A full account of this work will appear in *Biochimica et Biophysica Acta*.)

The number of flagella on the peritrichous bacteria varies considerably and even closely allied species may differ from one another in this respect. The typhoid bacillus, for example, has, as a rule, more flagella (ten to twelve) than the colon bacillus (two to six). The majority of actively motile bacteria belong either to the bacilli or spirilla, very few cocci are motile under ordinary

conditions. Within a given bacterial species different degrees of motility may be found. Some strains within a species may consist practically entirely of motile cells, while other strains may show no motility in hanging drop preparations nor may flagella be found in stained smears. Further, the motility of some strains is affected by the temperature of incubation while that of others is not, some strains may be motile when grown at 22° C. but not when grown at 37° C. Motility, therefore, is not a character that can be used for exact delimitation of species or varieties of bacteria. Standard cultural characters and biochemical reactions do not appear to be correlated with the presence or absence of motility.

Fig. 8 Spore formation by bacteria. Left, the anthrax bacillus which forms central spores which do not distend the wall of the vegetative cell, the tendency of the bacilli to occur in chains is also characteristic. Center, *Clostridium botulinum* type B, which shows the typical clostridial form with terminal spore of greater diameter than the vegetative cell, note the free spores separated from disintegrated vegetative cells. Right, *Clostridium sporogenes*, showing a subterminal clostridial spore. These preparations are all stained with a single stain in the usual way, the vegetative cells take up the dye but the spores remain unstained Fuchsin, $\times 1050$.

Spores.¹² Some of the bacilli possess the ability to form resistant structures known as spores. Such spores, spherical or oval in shape, show a relatively high resistance to all sorts of injurious influences, including high temperatures, germicidal chemicals, etc. Furthermore, they stain with great difficulty. Usually heat in combination with a mordant is necessary to drive the dye into them.

An assembling or concentration of nuclear material (i.e., material staining deeply with basic dyes) precedes spore formation in some cases and constitutes the spore primordium. Cytological studies suggest that in some bacteria a granule forms which enlarges to become the spore, in others there is an aggregation of granules, and in still others no granules are formed and what appears to be a condensation of the protoplasm occurs. The highly refractive character of the unstained spore and its reduced water content probably are connected with the concentrated character of the spore substance. Such spores

may be formed in any part of the cell, the position generally being relatively constant within a species. The spore is spoken of as *terminal* if formed at one end of the cell, *central* if formed in the center of the cell, and *subterminal* if formed half way between the center and the end of the vegetative cell. In some cases the spore does not exceed the diameter of the parent cell, as in the anthrax bacillus, in others where its diameter is greater than that of the vegetative cell it causes a bulging out of the wall of the cell at the point where it lies. If such spores are terminal, a drum-stick appearance may result, as in the tetanus bacillus; or if it is central, the vegetative cell becomes spindle-shaped. In simple stains the spore appears as an unstained round or oval body lying within the stained protoplasm of the vegetative cell. When the spore is fully developed, the vegetative cell disintegrates and disappears.

Fig. 9
spore ca
to end
hydrochloric acid fixation, Giemsa, $\times 4000$. (Robinow.)

The conditions under which bacteria form spores vary with the nature of the organism. The anthrax bacillus, an aerobe, forms spores only when in contact with free oxygen, a fact that has practical bearing on the disposal of bodies of cattle dead of the disease. The tetanus bacillus, on the other hand, and the anaerobes in general, form spores in the entire absence of oxygen. A suitable temperature is essential to the formation of spores. The anthrax bacillus forms spores most abundantly at 30°C to 32°C , and will not produce them at a temperature of 12°C . Lack of food is apparently not an adequate stimulus to spore formation. In all cases a period of uninterrupted vegetative multiplication precedes the appearance of spores, and the conditions necessary for their production seem to arrive simultaneously for most of the cells in a culture. It has been suggested that diminution in the water content of the bacterial cell, leading to a shrinking of the colloids, is the main factor in bringing about spore formation. Friedman and Henry¹³ have found that the percentage of bound water is relatively high in spores as compared with

vegetative cells, and suggest that this is associated with their heat resistance. In any case, spores are not formed under adverse conditions, as it might be thought, but in circumstances favorable to growth.

When spores are brought under conditions favorable for growth they *germinate* and become vegetative cells which multiply in the usual manner. The rate of germination has been found to be logarithmic¹⁴ but delayed germination occurs with some frequency and in some cases appears to be due to the presence of inhibiting substances, such as oleic and linoleic acids, in the culture medium rather than a delayed response to a favorable environment.¹⁵ As it undergoes germination the spore shows a change in its refractive properties, probably due to the imbibition of water. The entire spore wall may

become thin and stretch and the spore assume a bacillary form, or a vegetative cell may burst through the spore membrane, the empty case being cast off as a hull. The anthrax bacillus grows out of one side of the spore wall; the closely related hay bacillus grows out of opposite sides simultaneously. Other forms of bacteria exhibit intermediate methods of germination. Also, irregularities may occur in the development of spores of the same species. The process of development of the vegetative cell and its escape from the spore case is particularly well illustrated in the electron micrographs in Fig. 10, taken by Knaysi who has studied the process of sporulation in detail.¹⁶

¹⁴ Wynne and Foster Jour. Bact. 1948, 55 69.

¹⁵ See the general discussion of studies on this point by Foster and Wynne Jour. Bact., 1948, 55 623.

¹⁶ Knaysi: Jour. Bact., 1945, 49, 473, 617, *ibid*, 1946, 51 187. *ibid*, 1947, 53 525.

the tentative conclusions sponsored by different observers. One reason for this is that the point at issue has not always been clearly defined. Sometimes the problem actually submitted to experimental study has been the correlation between resistance to a particular bacterium and the presence of the corresponding antibodies in the circulating blood. But we shall see, when studying anaphylaxis, that specific antibodies readily become fixed to tissue cells; so that the demonstration of immunity in the absence of circulating antibodies, or a failure to find any close association between antibody titre and degree of resistance, cannot be accepted as satisfactory evidence that specific antibodies are not involved.

As an example of the relations that hold in experiments of this kind we may refer again to the studies of Wright (1927).

In these experiments, a large series of rabbits were immunized by a single intravenous inoculation of killed culture and were tested at various intervals thereafter by determining the rate at which virulent pneumococci disappeared from the blood stream, after the intravenous injection of 1 ml. of living culture. The results suggested that there was a slight, but definite, improvement in the clearing capacity within a few hours. This became well established on the 3rd day, was still marked at the end of a month, and might persist for 3 to 6 months, though in diminishing degree. The serum of many of these rabbits was tested for the presence of agglutinins, opsonins, and precipitins. It was found that the production of these antibodies was inconstant, and that the times of their appearance and disappearance in the blood in no way corresponded to the duration of the improved clearing capacity. In many cases no antibodies were ever demonstrable, although the rabbit showed a well-marked clearing reaction. In others, agglutinins appeared to low titre on the 4th day, increased in amount to the 7th or 10th day, and disappeared by the end of the 3rd week. Thus they first appeared after the increased clearing capacity had become well established, and vanished while it was still present in a marked degree. Wright also determined the inhibiting action of whole blood (heparinized) on the growth of pneumococci, using a modification of the methods employed by earlier workers in determining the bactericidal action of whole blood on this organism. He found that the results of this *in vitro* test were far more closely correlated with the clearing capacity of the rabbits, and with the power of their serum to confer this clearing capacity on normal rabbits, than were the results obtained by agglutination or precipitin reactions.

A protocol, taken from his paper, and slightly modified in form, affords a clear illustration of the general type of his results. (Table 71.)

The lack of correspondence between the presence of agglutinins and precipitins on the one hand, and clearing capacity on the other, is obvious; but the association between the growth-inhibitory action of the whole blood and the clearing capacity is very close. Similarly, those rabbits which are able to remove pneumococci rapidly and completely from their own circulating blood are in a position to confer a similar ability on normal rabbits, by the transference to the latter of a relatively small proportion of their blood serum. The correspondence, in this case, is not absolute; but the association is well-marked.

It should, perhaps, be noted that other workers have reported the occurrence of an effective active immunity in the entire absence of circulating antibodies, as judged by all available tests, including the bactericidal power of the whole blood (see, for instance, Teale 1935).

As we relate in Chapter 50, antibody may be formed locally in the connective tissue, by cells proliferating there in response to the antigenic stimulus. It is therefore possible that the immune response of the infecting organism in the connective tissue may be a locally effective response; but Nunes (1950) reports substantial amounts of agglutinin in the blood of guinea-pigs within 5 hours of an intraperitoneal injection of a massive infecting dose of pneumococci.

Spore formation is not very common among bacteria. It has been definitely observed only in the rod forms; cocci are not known to sporulate, and sporulating spirilla, if they exist, are rare. The majority of the obligate anaerobes produce spores, as do some of the aerobic bacilli. The spore-forming bacteria of known pathogenicity for man are few, a fortunate circumstance that materially facilitates and simplifies disinfection and the treatment of infectious disease. Physiologically, the spore is usually considered as a resting stage, serving to tide the species over unfavorable periods. From this point of view, the spore stage is analogous to the periods of hibernation or estivation among higher

Fig. 11. Electron micrograph of *Clostridium tetani* from 24 hour culture. The protoplasm is homogeneous at this stage and the clear cell walls are apparent. Peritrichous flagella are shown also, and the bacilli are in various stages of cell division. Compare the latter with Fig. 15. (Mudd and Anderson, SAB No. 61.)

forms of life and the living matter of the spore may remain dormant for years or even decades. It does represent a definite differentiation of the vegetative cell as indicated by the occurrence of antigens in the spore that differ from those of the vegetative cell as well as antigens shared by the two forms.¹⁷ Spore formation is not a form of multiplication, for each vegetative cell forms only a single spore and each spore germinates into a single vegetative cell. Obviously no increase in numbers is possible by this process.

The Finer Structure of the Bacterial Cell. Knowledge of the intracellular structures of bacteria is strictly limited, as pointed out above, by limits in the resolving powers of the microscope. Three questions have been of interest, namely: the existence and nature of the cell membrane, the nature of the cell substance or entoplasm, and, finally, the question of the existence of a nucleus.

¹⁷ See Doak and Lamanna: Jour. Bact., 1948, 55 369.

HUMAN ENCEPHALITIS

Encephalitis Lethargica.

This is a primary encephalitis, presumably of virus origin. The disease was first described by von Economo (1917) in Vienna, and was recognized in this country the following year. The highest year of incidence in England and Wales was 1924, when 5,039 cases were notified with 1,407 deaths. Since then the incidence has declined gradually, and by 1950 the number of registered deaths had fallen to 115. From post-mortem observations, however, it appears very doubtful whether more than a small proportion of the cases diagnosed as encephalitis lethargica are really examples of this disease. The true incidence is probably far lower than is indicated by the reported figures. *Epidemic hiccup* is regarded as a mild form of the disease (see MacNalty 1937).

Conflicting reports have been published on the aetiology of encephalitis lethargica. Much of the earlier work on the transmission of infection to animals was confused by the occurrence of a spontaneous disease of rabbits—meningo-encephalitis (see p. 2161)—and must be disregarded. Observations by Levaditi and Harvier (1922-23), Perdrau (1925*a, b*), da Fano and Perdrau (1927), and Gay and Holden (1933) suggest that the virus of encephalitis lethargica may be related to that of herpes, but this is little more than speculation. Though both McIntosh (1923) and McCartney (1924*b*) have reported the transmission of a fatal encephalitis to rabbits by the direct inoculation of brain suspensions from infected patients, it must be admitted that very little progress has been made in the study of this disease and its causation still remains obscure. (For a short summary of the experimental observations made on this disease the reader is referred to pages 1499-1501 in the 2nd edition of this book.)

The Arthropod-borne Group

This comprises a number of diseases conveyed, usually by mosquitoes, to man and sometimes the larger animals from a reservoir which may be in small mammals and birds or in insects. Many of the causative viruses are closely related to each other, and many form a haemagglutinin acting on the red blood corpuscles of sheep, pigeons, or newly hatched chicks (see Macdonald 1952, Chanock and Sabin 1953).

St. Louis Encephalitis.—A very remarkable outbreak of encephalitis occurred in St. Louis, Mo., during the late summer of 1933. The epidemic started at the beginning of August and finished about the end of October. Rather over a thousand persons were attacked—an incidence of approximately 1 per 1,000 of the population. The case-fatality rate, which had an average of 20 per cent., showed a striking increase in relation to the age of the patient, thus, under 40 years of age it was less than 10 per cent.; in the 40-50 age group it was 12 per cent., in the 50-60 group 21 per cent., in the 60-70 group 38 per cent., in the 70-80 group 56 per cent., and in the 80-90 group 80 per cent. Over half the fatal cases died in the 1st week. The incubation period was not determined with certainty, but appeared to be from 4 to 21 days. Pathologically, the lesions differed in several respects from those in encephalitis lethargica, particularly in the more extensive involvement of the meninges and spinal cord, the more widespread distribution of inflammatory foci through the brain, and the greater frequency of degenerative changes in the nerve cells and of neuronophagia (Report 1935).

Cultures of the blood and spinal fluid were sterile. Attempts to transmit the

The cell membrane of bacteria is not demonstrable as a structurally differentiated envelope, as that of many plant cells is, by immersion of the cells in hypertonic solutions. Robinow has found that treatment with boiling dilute sodium hydroxide results in a shrinkage of the protoplasm away from the cell wall, allowing its direct demonstration by staining with crystal violet. Such rigorous treatment may, of course, result in artifacts but a cell wall appears clearly in electron micrographs as shown in Fig. 11, and studies by Mudd and his associates¹⁸ with the electron microscope have shown that it is a definite morphological structure from which the cytoplasm may shrink away and which is sufficiently solid to show jagged lines of fracture when broken by sonic vibrations. It would appear to have considerable rigidity, particularly among the bacilli, in order to maintain shapes other than spherical. Experi-

Fig. 12. Irregular and bipolar staining of the plague bacillus. Note the heavily stained areas and metachromatic granules. Fixed in methyl alcohol and stained with methylene blue, $\times 2400$.

ments on the growth of the colon bacillus in media in which the surface tension had been reduced by the addition of sodium oleate resulted in the production of long, filamentous forms, much longer than the usual rods. Such experiments have been interpreted as indicating that this organism is essentially tubular, the sides having sufficient rigidity to withstand the reduced surface tension but the length increasing because of a less rigid structure at the ends.

Knaysi¹⁹ has found that the cell wall of *Bacillus cereus* and *Bacillus megaterium* is made up of lipid and protein in stable combination and is much more resistant to autolysis than the cytoplasm. It stains with dyes of the Sudan series, and he has found that the inner surface is jagged and irregular, tending to divide the cell into compartments. It is possibly this last that results in the lack of a sharply defined interface between the entoplasm and the outer cell wall in the usual preparations. The precise nature of the bacterial cell membrane is of particular interest in connection with the problems of permeability.

¹⁸ Mudd *et al.*: Jour. Bact. 1941, 41:415, *ibid.*, 1941, 42:251.

and his colleagues (1942*b*, *c*) isolated three strains of the St. Louis virus from *Culex tarsalis* Coquillett in the Yakima Valley and proved these insects to be capable of transmitting infection under experimental conditions. The real reservoir of infection, however, appears to be the mite, which infects chickens and—probably more important—wild birds in their nests. These birds develop a viremia which enables the mosquitoes to become infected and so transmit the disease to man (see Hammon *et al.* 1951). *Diagnosis* of the disease during life is aided by the complement-fixation test, which is usually positive within the first two weeks. Neutralizing antibodies appear later, but are less liable to give false positive reactions. At autopsy the organism may be isolated from the central nervous system by mouse inoculation.

Japanese B Encephalitis.—SYNONYM: *B encephalitis*; *Russian autumn encephalitis*.—In Japan several outbreaks of encephalitis have occurred during the past 100 years or so. They have been particularly common during the late summer months, and for this reason the disease is often referred to as “summer encephalitis.” A large outbreak occurred in the summer and autumn of 1924, when there were over 7,000 cases with a fatality rate of 60 per cent. Another large epidemic, causing about 5,000 deaths, was witnessed in August and September 1935. The American troops suffered in Okinawa (see Tigertt *et al.* 1950); and there was a severe outbreak in Korea in August 1949, lasting for about 6 weeks, with 5,548 reported cases and 2,429 deaths (Hullinghorst *et al.* 1951). The disease is said to be endemic in Malaya (Paterson *et al.* 1952), and possibly in the Sudan and Congo (Smithburn and Jacobs 1942). The incubation period is 8–15 days, most often 11–12 (Mosher 1947). Pathologically the disease is a meningoencephalitis, characterized by widespread cortical damage with ganglion cell degeneration, focal perivascular lymphocytic infiltration, destruction of the Purkinje cells of the cerebellum, and changes in the cord almost identical with those of poliomyelitis. Judged by the presence of neutralizing antibodies, inapparent infections are very common in the normal population, and in domestic animals such as the horse, cow, pig, and goat (Bawell *et al.* 1950).

Horses may also suffer from overt disease. Burns, Tigertt and Matumoto (1949) described an outbreak of encephalomyelitis in these animals, and isolated 2 strains of virus that were immunologically similar to, if not identical with, the virus responsible or infecting man.

For a general review of Japanese B encephalitis, see Warren (1946), Olitsky and Casals (1952).

The causative virus was isolated and studied by Kasahara and his colleagues (1936*a*, *b*, 1937*a*, *b*) and by Taniguchi and his colleagues (1936). It is about 20–30 μ in size (Yaoi *et al.* 1939); it can be cultivated in a medium of the Maitland type containing minced chick embryo brain (Kawakita 1939); it is avirulent to rabbits, but gives rise to a non-suppurative meningo-encephalomyelitis on intracerebral inoculation of mice, monkeys, and young sheep; it is neutralized by the serum of convalescent patients; and it can be distinguished by cross-neutralization tests from the virus of St. Louis encephalitis (Kawamura *et al.* 1936, Kasahara *et al.* 1937*a*, Webster 1938*a*) and from the West Nile virus (Casals 1944). Guinea-pigs are said by the Japanese workers (Kasahara *et al.* 1936*a*) to be susceptible to intratesticular inoculation, but they appear to be resistant to intracerebral inoculation (Webster 1938*a*). Albino rats 7 days old can be

The nature of the cell substance is not well known. It is, of course, protoplasm, as the ancillary evidence of chemical composition indicates. The cells of actively growing cultures appear to be homogeneous both in the unstained state and when stained by various dyes. As the culture becomes older, however, the cells of many organisms may be found to contain granular material which is somewhat more refractive than the surrounding protoplasm in the unstained state, and which takes up certain dyes with greater avidity than the remainder of the cell. These granules are called *metachromatic granules* or, after the workers who first described them, *Babes-Ernst granules*. They are sometimes scattered through the cell substance, and sometimes massed at either end, where they constitute the "polar granules" observed in the plague bacillus, the glanders bacillus and certain other bacteria. In certain species

Fig. 13. Metachromatic granules and bipolar staining in the diphtheria bacillus. Note the differences between these organisms and the plague bacilli. Methylene blue, $\times 1975$.

the metachromatic granules are particularly easy to demonstrate, and their abundance may even constitute a character of some differential value. The nature of these granules has been the subject of microchemical investigations, but the results are somewhat of polysaccharide material of designated *granulose*.

appear to consist of nucleoprotein and take up the nuclear stains with great avidity. This nucleoprotein has been termed *volutin*, and granules of this and other material are generally spoken of as "reserve material"—a term which, because of its implications, could hardly have been less wisely chosen.

The apparent lack of a discrete nucleus in the cells of the true bacteria has been a source of much speculation. Granular materials such as volutin and metachromatic granules which are characterized by staining deeply with basic dyes are sometimes referred to as "nucleoids" but apparently have no nuclear function. The seeming homogeneity of the cell substance, both in the stained and unstained states, has been interpreted by some to indicate that these cells

and his colleagues (1942b, c) isolated three strains of the St. Louis virus from *Culex tarsalis* Coquillett in the Yakima Valley and proved these insects to be capable of transmitting infection under experimental conditions. The real reservoir of infection, however, appears to be the mite, which infects chickens and—probably more important—wild birds in their nests. These birds develop a viremia which enables the

fixation test, which is usually positive within the first two weeks. Neutralizing antibodies appear later, but are less liable to give false positive reactions. At autopsy the organism may be isolated from the central nervous system by mouse inoculation.

Japanese B Encephalitis.—**SYNONYM:** *B encephalitis*; *Russian autumn encephalitis*.—In Japan several outbreaks of encephalitis have occurred during the past 100 years or so. They have been particularly common during the late summer months, and for this reason the disease is often referred to as "summer encephalitis." A large outbreak occurred in the summer and autumn of 1921, when there were over 7,000 cases with a fatality rate of 60 per cent. Another large epidemic, causing about 5,000 deaths, was witnessed in August and September 1935. The American troops suffered in Okinawa (see Tigertt *et al.* 1950); and there was a severe outbreak in Korea in August 1949, lasting for about 6 weeks, with 5,548 reported cases and 2,429 deaths (Hullinghorst *et al.* 1951). The disease is said to be endemic in Malaya (Paterson *et al.* 1952), and possibly in the Sudan and Congo (Smithburn and Jacobs 1942). The incubation period is 8–15 days, most often 11–12 (Mosher 1947). Pathologically the disease is a meningoencephalitis, characterized by widespread cortical damage with ganglion cell degeneration, focal perivascular lymphocytic infiltration, destruction of the Purkinje cells of the cerebellum, and changes in the cord almost identical with those of poliomyelitis. Judged by the presence of neutralizing antibodies, inapparent infections are very common in the normal population, and in domestic animals such as the horse, cow, pig, and goat (Bawell *et al.* 1950).

Horses may also suffer from overt disease. Burns, Tigertt and Matumoto (1949) described an outbreak of encephalomyelitis in these animals, and isolated 2 strains of virus that were immunologically similar to, if not identical with, the virus responsible or infecting man.

For a general review of Japanese B encephalitis, see Warren (1946), Olitsky and Casals (1952).

The causative virus was isolated and studied by Kasahara and his colleagues (1936a, b, 1937a, b) and by Taniguchi and his colleagues (1936). It is about 20–30 $m\mu$ in size (Yaoi *et al.* 1939); it can be cultivated in a medium of the Maitland type containing minced chick embryo brain (Kawakita 1939); it is avirulent to rabbits, but gives rise to a non-suppurative meningo-encephalomyelitis on intracerebral inoculation of mice, monkeys, and young sheep; it is neutralized by the serum of convalescent patients; and it can be distinguished by cross-neutralization tests from the virus of St. Louis encephalitis (Kawamura *et al.* 1936, Kasahara *et al.* 1937a, Webster 1938a) and from the West Nile virus (Casals 1944). Guinea-pigs are said by the Japanese workers (Kasahara *et al.* 1936a) to be susceptible to intratesticular inoculation, but they appear to be resistant to intracerebral inoculation (Webster 1938a). Albino rats 7 days old can be

consist entirely of cytoplasm and have no nucleus, and by others to mean that these cells are all nucleus and have no cytoplasm.

There is no doubt, however, that the bacterial cell contains relatively enormous amounts of nucleoprotein and nucleic acids demonstrable by microchemical methods such as the Fuelgen reaction, and the content of purine and pyrimidine nitrogen found by analysis is very high. It is clear that nuclear material is present in more than adequate amounts, and it has been customary to assume that the bacterial cell contains the chemical equivalent of a nucleus even though no morphologically differentiable structure could be demonstrated. More recently Robinow²⁰ has shown that the very faintly discernible areas apparent in bacteria stained with polychrome stains may be clearly shown by fixation with osmium tetroxide, differentiation in hot hydrochloric acid, and staining with Giemsa. He has called these chromatinic bodies, and their normal occurrence has received strong support from the studies of Hillier, Mudd and Smith²¹ who have found them in electron micrographs of preparations receiving no treatment other than drying. These chromatinic bodies are illustrated in both light and electron micrographs in Fig. 14. They show a strong morphological resemblance to nuclei, stain like nuclei with Giemsa, and appear to divide in the growing cell just prior to fission. Whether they represent true nuclei, analogous to those of other cells, remains to be fully established, but the implication that they are seems very strong.

COLONIAL MORPHOLOGY

A single bacterial cell or group of cells, when planted on a semisolid medium and allowed to develop under suitable conditions of moisture, temperature and air supply, will, in a few hours or days, develop a "colony" so large that it can be plainly seen with the naked eye. In many instances such masses of cells, particularly when the growth occurs on certain culture media, possess salient peculiarities which are characteristic of the species. Growths upon nutrient gelatin are especially characteristic, but upon nutrient agar the morphology of bacterial colonies is less distinctive. Colonies on potato and other solid food substances are, as a rule, still less characteristic. As was pointed out previously, colonial differences may often be accentuated by growth on media containing dyes and other compounds. Diphtheria bacilli, for example, form highly characteristic colonies on media containing potassium tellurate. The character of colonies is also somewhat affected by the density and viscosity of the culture medium and by the physical conditions under which the organisms develop. In general, however, the colony characteristics of a bacterial species are distinctive and are an aid in the isolation and identification of the organism. These characteristics include the size of the colony, its form—whether raised, flat, etc.—and the shape of its edges; its consistency and texture; its surface—whether roughened or smooth; its color, and other similar peculiarities.

These colony characteristics in many cases have their roots in the mor-

²⁰ Robinow. Jour. Hyg., 1944, 43, 413.

²¹ Hillier, Mudd and Smith. Jour. Bact., in press, personal communication from Dr. Mudd.

the brain after death. It is 15-25 μ in diameter. It grows on the chorio-allantoic membrane of the developing chick embryo. It is pathogenic to mice on subcutaneous as well as on intracerebral inoculation. It is virulent for sheep, moderately virulent for rhesus monkeys, and non-virulent for guinea-pigs and rabbits. The disease occurs in the spring and summer months, and is transmitted by the bite of the tick, *Ixodes persulcatus* Schulz. Numerous wild animals and birds are susceptible to experimental inoculation, and natural infection has been found in some rodents. It seems probable, however, that the tick constitutes the natural reservoir, since infection is transmitted by the ovarian route from generation to generation. The disease leaves behind it a lasting immunity. Neutralizing antibodies are demonstrable in the patient's blood about the end of the 2nd week but do not reach their maximum for 2-3 months.

Apart from the Far Eastern type, there is a Western type of spring-summer encephalitis that appears to occur not only in western Russia but also in Czechoslovakia (Krejci 1949, Rampas and Gallia 1949). It is a milder disease and has a lower case-fatality rate. Whether the viruses responsible for these two types are identical with each other is still doubtful, but both of them are very closely related to the virus of louping-ill. Pond, Russ and Warren (1953), who compared strains of Russian and Czechoslovakian encephalitis viruses with the louping-ill virus, concluded that, though there were minor differences between them, they must all be regarded as belonging to a single virus. For a general review of Russian spring-summer encephalitis, see Warren (1946), Olitsky and Casals (1952).

Encephalomyelitis due to Equine virus.—As its name implies, equine encephalomyelitis is essentially a disease of horses (see below). During the late summer and early autumn of 1938 there was a large outbreak in the United States, and human cases of the disease were recognized for the first time. An even larger outbreak affecting nearly 3000 persons occurred in 1941, mainly in North and South Dakota and Minnesota. Diagnosis of infection with the eastern type of virus was made by Fothergill, Dingle, Farber and Connerley (1938) and by Webster and Wright (1938), and with the western type of virus by Howitt (1938b). The disease occurred in rural areas, and affected particularly infants and young children, in whom it caused a high mortality. The virus can sometimes be demonstrated in the blood (Howitt 1939) and in the cerebrospinal fluid (Fothergill, Holden and Wyckoff 1939) during life. After death it may be isolated from the brain by intracerebral inoculation of mice. Neutralizing antibodies are often present in the blood serum and the cerebrospinal fluid of convalescent patients (Howitt 1941, Buss and Howitt 1941). Healthy contacts who have been exposed to infection may also have neutralizing antibodies (Mitchell and Pullin 1943). Diagnosis during life may be made by the demonstration of complement-fixing and neutralizing antibodies in the patient's serum (Casals and Palacios 1941, Casals 1941, Howitt 1943). Infection is probably carried by mosquitoes—*Culex tarsalis* Coquillett (Hammon *et al.* 1942a, b). Besides the disease due to the eastern and western types of virus, laboratory infections have been described with the Venezuelan type (Casals *et al.* 1943).

Encephalitis due to other Viruses.—Several other arthropod-borne viruses are known that cause or are suspected to cause encephalitis. Three of these—the West Nile, the Bwamba, and the Mengo viruses—were isolated from human cases in East Africa; others, such as the Semliki Forest, the Bunyamwera, the Ntaya, the Zika and the Uganda viruses in East Africa, the California virus in the United States, the Ilheus virus in Brazil, and the Anopheles A and B and Wyeomyia

Fig. 14. The chromatinic bodies of *Bacterium coli* which are interpreted as representing the bacterial nuclear apparatus. The upper section of the plate is an electron micrograph of an unfixed preparation from a 3 hour culture of *Bact. coli*. The light areas within the bacterial protoplasm correspond with those faintly discernible with the light microscope and clearly discernible after fixation with osmium tetroxide vapor. (Hillier, Mudd and Smith,

viruses in Colombia, were isolated from mosquitoes. They were detected by virtue of their neurotropic properties for mice. Surveys in Uganda and Tanganyika showed the presence of neutralizing antibodies in some samples of human serum against the Bwamba, the Ntaya, the Zika, and occasionally the Mengo virus, indicating that these viruses were able to infect man (Smithburn 1952); and three cases of febrile disease associated with the Zika virus have since been described (Macnamara 1951). Antibodies were also found to the Ilhéus virus in natives of Brazil (Southam and Moore 1951). Whether, and if so how often, these viruses infect the central nervous system of man is so far undetermined, though human volunteer experiments have shown that the Ilhéus and the Bunyamwera viruses are able to cause encephalitis (Southam and Moore 1951). According to their size estimated by filtration they fall into 3 groups: (1) Anopheles A and B, Wyeomyia, Ntaya, Bwamba fever, and Bunyamwera viruses ranging from 70-122 $m\mu$ in diameter; (2) West Nile, Semliki Forest, Kumbia, Zika, Ilhéus, and Uganda S viruses of 18-30 $m\mu$; and (3) Mengo virus of 10-15 $m\mu$ (Smithburn and Bugher 1953). We append short notes on some of these viruses.

West Nile virus.—This virus was isolated in 1937 from the blood of an African woman suffering from a mild febrile disease. Neutralizing antibodies were subsequently demonstrated in her serum (Smithburn *et al.* 1940). The virus is pathogenic for mice and monkeys injected intracerebrally, and produces in the Purkinje cells of the cerebellum degenerative changes similar to those found in Japanese B encephalitis and in louping-ill. It is estimated to be 21-31 $m\mu$ in diameter. Immunologically it is closely related to the St. Louis and the Japanese B encephalitis viruses (Smithburn 1942). There is evidence that the virus is widespread in Egypt and Equatorial Africa. Goldblum, Sterk and Paderski (1954), who isolated it from 9 cases in Israel, found that the disease to which it gave rise was characterized by an incubation period of 2-6 days, a sudden onset with fever, drowsiness, frontal headache, aching of the eyes on movement, and general enlargement of the lymph nodes. The illness lasted 3-6 days, but convalescence was slow and the lymph nodes took 1-2 months to go down. A rise in the titre of complement-fixing antibodies was demonstrated. According to Smithburn (1954), the West Nile and Ntaya viruses are related to each other and to the virus of Japanese B encephalitis.

Bwamba Fever.—A mild non-fatal disease, caused by a virus producing nervous symptoms in mice, was encountered in African natives by Smithburn, Mahaffy and Paul (1941) during a yellow fever survey in the Western Province of Uganda and was named by them Bwamba fever. Clinically, the disease was characterized by a sudden onset with fever, headache, and pain in the lumbar region, mild conjunctival injection and a skin rash. The fever lasted for 2-5 days, the headache and backache for 2 or 3 days longer. Convalescence was rapid and complete. The disease did not appear to be highly contagious. A virus could be demonstrated in the blood by intracerebral inoculation of mice, and could be carried over from one mouse to another by injection of brain tissue. After intracerebral injection symptoms of nervous excitement appeared in about 4 days, and the animals generally died a day later. At post-mortem there was a variable degree

developed a non-fatal febrile illness when injected intracerebrally. Rabbits proved resistant. The virus passed through a Seitz filter. Judged by experiments with gradocol membranes its size was between 113 and 150 $m\mu$ (now given as 75 and 113 $m\mu$). It could be readily preserved by drying from the frozen state, but a saline suspension kept in the ice-chest proved innocuous within 13 days. It was destroyed by exposure to heat at 50° C. for 30 minutes. Antibodies specifically neutralizing the virus

phology of the individual cells. The movements of cells after fission and the arrangements that result determine, to a considerable extent, the texture of a colony and the shape of its edges. The long coiled filaments of the anthrax bacillus give the colony of this organism its characteristic "medusa-like" appearance. The presence of capsules on an organism gives its colonies a slimy consistency, and their absence a dry, roughened appearance. The colonies of some bacteria show coloring due to the elaboration of pigments by the organisms, but such pigments are not apparent in the individual cell under the microscope. Yellow and golden pigments are not uncommon, and others, including red, blue-green and violet, are met with from time to time.

ditions of life, and can be regarded as only one item in the sum total of characters that go to make up the concept of a bacterial species. One difference between colony types which has recently been discovered appears to be of deep-seated significance. In a number of bacterial groups it has been found that rough (R) and smooth (S) colonies will develop from a single, apparently pure, culture (p. 165). Under ordinary conditions, transfers from S and R colonies often breed true. The rough and smooth strains differ in virulence and other characteristics, and the marked and persistent association of colony characters with physiological and biochemical qualities may be of considerable biological significance.

BACTERIAL GROWTH

Although bacterial growth may be, and often is, assumed to be a simple process, both experimental evidence and theoretical considerations indicate that the problems of growth are relatively complex. It is convenient to consider bacterial growth under two general heads: first, the process of cell division or multiplication, and, second, the growth of bacterial populations.

Growth and Cell Division. By all odds the most common method of division is that of simple fission which divides the cell into approximately equal halves. Among bacilli and spirilla, cell division usually takes place at right angles to the long axis of the cell. The cocci may divide in one, two or three planes, thus giving rise to characteristic groupings such as chains, flat sheets or irregular masses, or cubical packets. Bacilli and spirilla show some elongation before division, cocci, as a rule, do not, although some exhibit an increase in the diameter of the cell without any alteration of its spherical form. The size which a single cell must reach before fission is, as among the higher forms of life, singularly constant for each species although, as will appear, some differences in this maximum size appear to be associated with the age of the culture.

Jour. Bact., 1949.) The center section is a light photograph of a young culture of *Bact*

critical illumination after Kohler. The chromatonic bodies are clearly apparent as the dark areas. (Robinson.)

following respects: (1) they produce a rapidly fatal disease in the mouse, hamster, and cotton-rat, a disease of variable severity in the guinea-pig, and an inapparent infection in the albino rat, rabbit, and rhesus monkey; (2) they are readily cultivated in the fertile hen's egg; (3) they are pantropic, rapidly appearing in the blood stream and reaching high concentrations in the viscera of susceptible animals; (4) under appropriate conditions viscerotropic strains cause acute interstitial myocarditis in the mouse characterized by necrosis of the muscle fibres and an inflammatory cellular reaction; (5) the lesions produced in the central nervous system are those of a diffuse poliomyelitis; (6) they are of small size, that of the Mengo virus estimated by filtration being 8-12 μ (Dick 1948), the Columbia S.K. virus estimated by electronmicrography at 25-30 μ (Jungeblut and Bourdillon 1943), and the encephalomyocarditis virus estimated by electronmicrography at 27-33 μ (Weil *et al.* 1952); (7) they agglutinate sheep red blood corpuscles (Olitsky and Yager 1949); (8) they appear to be natural parasites of the mouse, rarely infecting man; (9) they may be carried by mosquitoes.

Meningo-encephalitis of Unknown Origin.—It should be made clear that large numbers of sporadic cases of encephalitis occur in which the cause remains obscure. Some of these are undoubtedly manifestations of poliomyelitis, but the aetiology of others is unknown. Occasionally outbreaks are observed, such as those recorded by Jennings (1947) in England and Humbert and his colleagues (1947) in Tennessee. Further work is clearly required.

Secondary Encephalitis.—We have already (p. 2122) drawn attention to the encephalitis that occasionally follows vaccination against smallpox, and have discussed its aetiology. Similar cases of encephalitis sometimes occur during convalescence from other diseases such as measles, varicella, mumps, yellow fever, and influenza. The most striking characteristic of all these cases is the occurrence of perivascular demyelination—a lesion which is not usually met with in primary encephalitis. Whether the production of secondary encephalitis is due to the virus causing the primary disease, or to a different virus lying latent in the tissues, or is a purely degenerative condition not determined by a virus at all, has been a subject for debate (see McIntosh 1928, McIntosh and Scarff 1928, Greenfield 1930, Rivers 1932, Ledingham 1935, Hurst 1936). More recent work, which is reviewed by Hurst (1952), points strongly in favour of an allergic aetiology.

For a description of the clinical and pathological manifestations of the various types of encephalitis in human beings, the reader is referred to the monograph by Neal (1942).

ENCEPHALITIS IN ANIMALS

Borna Disease. Endemic Encephalomyelitis of Horses, Cattle and Sheep.

Borna disease is the name given to an infectious encephalomyelitis of horses. The name "Borna" is derived from the locality in Saxony where a severe epizootic occurred during the years 1894-96. The disease is widely distributed, and may occur in epidemic form with a mortality sometimes reaching 90 per cent. A similar encephalomyelitis is likewise observed in cattle and sheep. Histologically, lesions are found in the central nervous system and in the peripheral nerves, and characteristic inclusions (Joest-Degen intranuclear corpuscles) are observed in the large ganglion cells of Ammon's horn. The disease is due to a filtrable virus, which appears to be the same in all three species of animal. According to Elford and Galloway (1933b) it is about 85-125 μ in diameter. The virus is resistant to glycerol, but

While bacterial multiplication is commonly observed to take place by simple transverse fission, other modes of cell division may occur. Some forms, such as the diphtheria bacillus and the tubercle bacillus, show Y-like splitting and true branching characteristic of some of the higher fungi. Budding, similar to the budding of yeast cells, has been reported by some observers. More complex processes, such as the formation within a mother cell of a number of viable granules, called gonidia, which, upon liberation, develop into typical bacillary forms, have been reported by other workers. The status of the great majority of these observations has been open to some question since many of the structures reported were too small to have been resolved by the light microscope. The electron microscope, however, allows the resolution of

Fig. 15. Electron micrograph of *Lactobacillus acidophilus* showing various stages in cell division. The initial slight constriction, deeper constriction, and partially separated daughter cells are all shown. Note the light cell walls surrounding the dense black protoplast, and the diploid cells connected by a delicate strand of protoplasm. (Mudd, Polevitsky and Anderson, SAB No. 78.)

very minute structures and with it Smith, Mudd and Hillier²² have observed a kind of reproductive process in the *Bacteroides* (p. 540) and pleuropneumonia-like organisms (p. 548) in which these structurally fragile cells swell to form large round bodies that then may undergo multipolar germination. The outgrowing processes segment to form numbers of daughter cells. Whether such processes are of common occurrence among other kinds of bacteria is not clear.

The possibility of the occurrence of conjugation, and inferentially a sexual stage in reproduction, has been raised repeatedly but without adequate supporting evidence. Recently, however, Tatum and Lederberg²³ have reported the occurrence of mixed biochemical types of *Bact. coli* produced in mixed culture of strains derived from a single parent by x-ray irradiation and differ-

of the cranial nerves is doubtful (see Hurst 1950). The horse is therefore *infective* for the mosquito during only a brief period. This is an additional reason for believing, as Tenbroeck, Hurst and Traub (1935) suggested, that the horse is not the primary reservoir of infection.

The cause of the western type of the disease was found by Meyer, Haring and Howitt (1931) to be a filtrable virus. A similar virus, differing from it immunologically was later shown by Ten Broeck and Merrill (1933), Howitt (1935), Records and Vawter (1935) and Shahan and Giltner (1935) to be responsible for the eastern type. Both viruses are estimated to be about 20-35 μ in diameter (Bauer *et al.* 1935, Tang *et al.* 1937), though Sharp and his colleagues (1943) give a figure of about 50 μ . They can be grown readily in tissue culture and on the chorio-allantoic membrane of the developing chick embryo. They remain viable in 50 per cent. glycerol in the ice-chest for a long time, but are readily destroyed by formalin. The eastern type is said to be more pathogenic than the western for guinea-pigs and rabbits, but both have a wide range of pathogenicity. Young animals are much more susceptible than old (Hurst 1950). The Argentine type of virus studied by Howitt (1935) appears to be identical with the western type, but the Venezuelan type, described by Beck and Wyckoff (1938) and Kubes and Ríos (1939), is immunologically distinct.

In protection against equine encephalomyelitis inoculation with a formalized chick embryo vaccine, using the technique of cultivation described by Higbie and Howitt (1935), appears to be hopeful (see Eichhorn and Wyckoff 1938, Fothergill 1941b).

Encephalitis of Rats.—A virus, possibly related to the eastern equine encephalitis virus, giving rise to encephalitis in rats, was recognized by Novy, Perkins, Chambers and De Kruif (1953) when studying *Treponema novyi* in 1909, and described by Jordan, Nungester and Preston (1953), who recovered it from blood that had been put into sealed tubes 40 years earlier. The virus is about 20 μ in diameter, and gives rise to the disease experimentally on intraperitoneal or intracerebral injection. After an incubation period of 3-6 days, there is anorexia, roughening of the coat, apathy, gradual inability to walk, glazing of the eyes, and slight hæmaturia. Death follows in 1-2 days preceded by convulsions.

Encephalomyelitis of Mice.—This disease was described by Theiler (1937) in the United States, Gildemeister and Ahlfeld (1938) in Germany, and Iguchi (1939) in Japan. It is characterized by flaccid paralysis of the limbs and sometimes convulsions. Infection can be transmitted by intracerebral, intranasal and intraperitoneal inoculation. After intracerebral inoculation of mice there is an incubation period of 5-30 days. Flaccid paralysis then develops, usually affecting the fore limbs first, but being more severe in the hind limbs. Death usually follows 5-10 days after the onset of paralysis, but some animals survive and remain carriers for a time. Paralysed and carrier mice are resistant to a second intracerebral inoculation. There is evidence that immunity depends on the presence of neutralizing antibodies in the blood serum. Histologically, perivascular cellular infiltration is found throughout the central nervous system; there is acute necrosis of the ganglion cells, particularly in the anterior horn, followed by neuronophagia. After intramuscular inoculation there is myositis. No inclusion bodies appear to have been demonstrated yet.

The virus is one of the smallest known—9 to 13 μ —resembling in this respect the virus of poliomyelitis. It is readily destroyed at temperatures above 50°C,

ing in growth requirements. It is very difficult to interpret this evidence on other than the basis of a gene recombination arising through conjugation between the cell types. These observations have been confirmed by Haas, Wyss and Stone,²⁴ who have also observed an apparent fusion of chromatinic bodies on recovery from irradiation. Whether this last is to be interpreted as cytological evidence of a nuclear fusion and recombination of mutant characters is not clear.

While, then, a number of kinds of reproduction occur among the bacteria, binary fission is by far the most common. Under favorable conditions cell division may take place quite rapidly, as short a time as twenty minutes elapsing between one division and another of the colon bacillus. This rapidity of cell division is sometimes referred to as if it were a peculiar quality of bacteria, but as a matter of fact the embryonic cells of many higher forms of life divide quite as rapidly as bacteria. The remarkable thing about bacterial cell division is not so much the rapidity with which one cell division succeeds another as the fact that a very short time suffices for the growth of the young cell to maturity. A young bacterial cell attains full size and acquires the capacity to produce, in its turn, an independent organism much sooner than most other forms of life. This rapid reproduction of distinct individuals is plainly different from the multiplication of embryonic cells among higher organisms.

The Growth of Bacterial Populations. For obvious practical reasons bacteria are ordinarily manipulated and studied in groups consisting of large numbers of individuals. Likewise, bacterial growth is of practical significance, not in terms of one, two or three cell divisions, but as growth in populations which often reach a density of three to four hundred million cells per cubic centimeter of culture fluid. Growth of these organisms in culture may be considered from a variety of points of view, the particular one adopted being dependent upon the nature of a given investigation. A simple view that is commonly, if tacitly, taken assumes that growth may be described by the reaction

which proceeds from left to right and eventually comes to an equilibrium. The reaction velocity constants may be determined either by the rate of disappearance of the reacting substances or the rate of appearance of end products. Although complicated by a variety of side reactions, the assumption of such a relation has been extremely useful in the studies on bacterial metabolism. The growth of autotrophic bacteria, for example, is conveniently measured in terms of the conversion of carbonate to the organic carbon of protoplasm. A somewhat more mechanistic concept is that of the instability of an inoculated culture medium which, after undergoing a series of complex changes, reaches a stable equilibrium at a considerably lower energy level. Such a concept is, of course, the basis of studies of the energy metabolism of bacteria. These and similar views are oversimplified and, although of undoubted value, present only limited aspects of the phenomena of bacterial growth.

²⁴ *Proc. Nat. Acad. Sci.* 1948, 34 229.

The virus is about 10-15 μ in diameter. It seems to be moderately resistant to drying, and is destroyed by heating at 70° C. for 30 minutes (Fortner 1942). During life it can be demonstrated in the cerebrospinal fluid of sick animals, and occasionally in the faeces during the pre-paralytic stage, by inoculation into pigs. It has so far not been cultivated *in vitro* or in the fertile egg. In animals infected by the mouth it is said to be present in the blood during the early part of the incubation period, though not later. Animals that recover have neutralizing antibodies in the serum and are permanently immune. Their serum, however, has apparently no protective or curative action as ordinarily administered. The value of protective vaccines is doubtful. The slaughter policy is recommended by Klobouk (1952). (For further information see Fortner 1942, and Kaplan and Meranze 1948, who review the disease.)

Encephalomyelitis of Coypus.—Wenkebach (1952) described the epizootic occurrence of acute and chronic encephalomyelitis in the coypu (*Myocastor coypus*)—the nutria of the fur trade—in Argentina. It is caused by a virus named the *Maruen virus* after the neighbourhood in which it was first recognized. In man the virus produces a disease often diagnosed as influenza. It is pathogenic for mice, guinea-pigs, rabbits and cats. It can be grown in the fertile hen's egg. In sick animals it is found in the central nervous system, blood, lungs, liver and spleen. Histologically intranuclear and intracytoplasmic acidophilic Feulgen-negative inclusion bodies are demonstrable in the brain.

Infectious Paralysis of Guinea Pigs.—This disease occurs sporadically in guinea-pigs, and closely resembles poliomyelitis. According to Romer (1911), who first described it, it can be transmitted to normal guinea-pigs by the intracerebral inoculation of filtered or unfiltered brain or cord suspensions. After an incubation period of 9 to 22 days, the animals become febrile and lose weight; nervous disturbances develop, consisting of a gradually increasing muscular weakness, particularly of the hinder parts of the body; paralysis of the hind legs develops, and occasionally of the bladder. The disease lasts from 3 days to 3 weeks. Pathologically, the lesions are those of a disseminated meningo-myeloencephalitis. They differ from those of poliomyelitis in showing greater meningeal infiltration, and in being most severe around the central canal of the cord. The virus is constantly present in the central nervous system; it is also found in the prevertebral, inguinal, and mesenteric lymph glands, and occasionally in the liver and spleen.

Infectious Encephalomyelitis of Chickens.—This disease, which is sometimes referred to under the name of "epidemic tremor of chickens," was reported by Jones (1934) in New England. It is characterized by tremor, most noticeable in the head and neck, and progressive ataxia, either or both of which may be present in a single bird. Young chickens are mainly attacked, the usual age of onset being about 3 weeks. In commercial flocks the morbidity ranges from 5 to 50 per cent. In severe outbreaks about half the chicks may die; death is due to inanition caused by the progressive ataxia. Histologically, focal collections of glia cells, perivascular infiltration, and degeneration of nerve cells, especially of the Purkinje cells in the cerebellum, are found in the central nervous system. No inclusion bodies have yet been demonstrated. The disease can be reproduced in young chicks by intracerebral inoculation of brain and cord from affected birds. The incubation period of the experimental disease is usually 2-4 weeks; death follows about a week after the onset of symptoms (van Roekel *et al.* 1938). The infective agent is probably fairly large, since it can pass through a Berkefeld N

The existence of bacteria in large aggregations or *populations* is of no little significance because *ipso facto* they are subject to the principles of population mechanics. The potential multiplication of these organisms by geometrical progression may be realized only up to a certain point. As numbers increase in the microcosm of the test tube, competition between individual organisms for foodstuffs, oxygen and the like progressively reduces the opportunity for further growth until a saturating population is reached.

If no increasingly effective retardation were operative, the potential increase in a population would be expressed by the relation

$$\frac{dY}{dt} = bY$$

where Y is equal to the number of individuals per unit volume and b to the potential rate of multiplication of each organism. When, however, there is a maximal possible population, K , this potential geometric increase is only partially realized, the extent of the realization depending on how near the size of the population is to its maximum at any given moment. Or, mathematically,²⁵

$$\frac{dY}{dt} = bY \frac{K - Y}{K}$$

This equation is the differential equation of the logistic curve the mathematical form of which is.

$$Y = \frac{K}{1 + e^{a - bx}}$$

This function, plotting as a symmetrical sigmoid curve, has been found to describe, with a high degree of precision, the growth of populations of a variety of organisms including man, yeasts, *Drosophila*, certain protozoa, etc.

If the numbers of bacteria in a growing culture are determined from time to time and plotted against time, the points fall on a similar sigmoid curve. The resulting curve is, however, asymmetrical in that the point of inflection is not halfway between the upper and lower asymptotes but is considerably near the lower asymptote. This discrepancy between bacterial populations and populations of other organisms has not as yet been satisfactorily explained.

Partly as a consequence of this discrepancy and partly as a result of the large error inherent in the enumeration of bacteria, the treatment of bacterial growth curves has taken a slightly different path. Such curves are ordinarily not plotted arithmetically but on semilog paper; *i.e.*, the logarithms of the numbers of bacteria are plotted against time. This procedure has the advantage that not only are the errors of enumeration minimized but, when the organisms are multiplying at a geometric rate, the points fall on a straight line and the generation time determines the slope of this line. Furthermore, the numbers of viable bacteria, as determined by plate count, decline not long after the maximum population has been reached and the organisms appear to die off at a geometric rate. The equilibrium predicted by the logistic function is

²⁵ For a more detailed discussion of such rationalization the student is referred to Lotka's *Principles of Physical Biology*. Williams & Wilkins Company, Baltimore. 1925.

(see p. 2035 and Pool *et al.* 1930, Alston and Gibson 1931, Brownlee and Wilson 1932, Gordon *et al.* 1932, MacLeod and Gordon 1932, Gordon 1934). The disease may also be transmitted to monkeys (Hurst 1931a) and to field voles (Findlay and Elton 1933). Both mice and monkeys can be infected by intranasal as well as by intracerebral inoculation (Elford and Galloway 1933a, Galloway and Perdrau 1935). The virus is about 15–20 μ in diameter (Elford and Galloway 1933a). It can be cultivated in the fertile egg and in chick embryo tissue culture. It may infect man and give rise to meningo-encephalitis, usually after a prodromal illness resembling influenza (see Lawson *et al.* 1919). Most of the cases have occurred in laboratory workers. Neutralizing antibodies are detectable in the patient's serum within a few days and persist for years. Diagnosis may be made during life by injection of the blood or cerebrospinal fluid into mice. Sheep may be actively immunized by means of a 0.35 per cent formolized vaccine made from sheep brain, cord, and spleen, but there is a danger of conveying scrapie (see p. 2187) by such a vaccine (Gordon 1916). Passive immunity may be conferred on lambs born of non-immune mothers by subcutaneous injection of antiserum at birth (Wilson and Gordon 1948). For human beings exposed to special risk of infection a vaccine prepared from formolized mouse brain is suggested (Edward 1918).

LYMPHOCYTIC CHORIOMENINGITIS PSEUDO-LYMPHOCYTIC CHORIOMENINGITIS DURAND'S DISEASE

These three diseases may be considered together. In 1925 Wallgren coined the term "acute aseptic meningitis" to comprise cases of an acute febrile disease, accompanied by meningeal irritation and sometimes by inflammation of the upper respiratory tract, terminating favourably within 10–14 days. Since then benign lymphocytic meningitis, as it is sometimes called, has been found to be of varied aetiology. It is sometimes met with, for example, during the course of mumps and glandular fever, it is not at all an uncommon manifestation of human infection with *Leptospira canicola*; and it is a dominant feature in the disease of swineherds (see p. 2054), which is caused by *Leptospira pomona*. In this section we shall deal with the virus of (1) lymphocytic choriomeningitis, which has been reported chiefly from the United States and occasionally from other countries; (2) pseudo-lymphocytic choriomeningitis, which has been isolated on only two occasions—both in Great Britain, and (3) Durand's disease, of which only one case has been recognized—in Tunis.

Lymphocytic Choriomeningitis.

Armstrong and Lillie (1934), while investigating a fatal case of St. Louis encephalitis, isolated a virus, quite different from the ordinary St. Louis virus, which gave rise in experimentally inoculated monkeys and mice to a lymphocytic choriomeningitis. An apparently identical virus was isolated by Scott and Rivers (1936) (see also Rivers and Scott 1936) from two benign cases of non-bacterial lymphocytic meningitis in adult males in the United States, and by Findlay, Alcock, and Stern (1936) in this country from the cerebrospinal fluid of two patients who exhibited vague nervous symptoms following a febrile attack. A similar or identical virus was isolated by Findlay and his colleagues from an irradiated mouse showing

not realized unless experimental conditions are such that the food supply is constantly renewed and the waste products are removed. Such an equilibrium is attained, for example, in cultures in constantly flowing culture medium and the viable count tends to attain and persist at a constant level though the total count continues to rise, i.e., multiplication balances the death rate, but the dead cells accumulate.²⁶ A graphic representation of the rise and decline in numbers of viable bacteria in culture is given in Fig. 16.

Fig. 16 Diagrammatic representation of a bacterial growth curve, numbers of viable organisms plotted against time of incubation. A, initial stationary phase, B, positive growth acceleration phase, C, logarithmic growth phase, D, negative growth acceleration phase, E, maximum stationary phase, F, phase of accelerated death, G, logarithmic death phase. (After Buchanan.)

Buchanan²⁷ has divided this curve up into seven parts which he designates as follows.

- A *Initial Stationary Phase*. During this phase the number of bacteria remains constant.
- B *Lag Phase or Positive Growth Acceleration Phase*. During this phase the generation time decreases progressively until a minimum is reached.
- C *Logarithmic Growth Phase*. In this phase the generation time remains constant and the organisms increase in numbers by geometrical progression.
- D *Negative Growth Acceleration Phase*. The generation time progressively increases during this phase and the bacteria continue to multiply but at a decreasing rate.
- E. *Maximum Stationary Phase*. Here the numbers of viable bacteria are at a maximum, neither increasing nor decreasing.
- F *Phase of Accelerated Death*. Following the stationary phase, the numbers of viable bacteria decrease, slowly at first but with increasing rapidity, until a relatively constant rate is attained.
- G *Logarithmic Death Phase*. During this phase a constant rate of death is maintained. It should be noted that this rate is not maintained indefinitely for the curve tends to become asymptotic to the X axis.

Different explanations have been offered to account for the varying growth rates observed in bacterial cultures. The failure of inoculated organisms to

antigen of protein nature can be demonstrated in the virus by precipitin and complement-fixation reactions (Smadel *et al.* 1939, 1940). It appears to be different from the antigen that reacts with neutralizing antibodies in immune serum.

Diagnosis.—The cerebrospinal fluid is usually under pressure and contains an excess of lymphocytes, though this is not invariable. The globulin is often increased; the sugar may be low and the chlorides normal. The virus can be demonstrated in the blood and throat washings, or in the cerebrospinal fluid soon after the onset of meningeal symptoms, by inoculation intracerebrally into mice derived from a known non-infected stock, and its identity may be determined by neutralization with specific sera or by a specific complement-fixation reaction (Smadel and Wall 1941). Indirectly, the diagnosis may be assisted by the demonstration of complement-fixing antibodies (see Casals and Palacios 1941) or of neutralizing antibodies (Armstrong and Wooley 1935, Wooley *et al.* 1937) in the patient's serum. Complement-fixing antibodies appear within the first 3 weeks, neutralizing antibodies not for 6-10 weeks. Serum should be taken at the beginning of the disease, and again after 4-12 weeks according to the test that is to be used. Unlike the complement-fixing antibodies, which disappear within a few months, neutralizing antibodies persist for years.

Pseudo-lymphocytic Choriomeningitis.—Only two cases of this disease have so far been described. Clinically, they resembled benign lymphocytic choriomeningitis. MacCallum and his colleagues (1939) isolated a virus from the cerebrospinal fluid of each of the patients. It was considerably larger in size—150 to 225 μ —than the true choriomeningitis virus. It gave rise in mice, guinea-pigs, and *rhesus* monkeys to a clinical and pathological picture very similar to that of choriomeningitis, except that in mice inoculated intracerebrally the incubation period was shorter—4 to 5 days instead of 5 to 12 days—and the pathological lesions were less extensive. Judged by cross-immunity tests in mice, the two viruses appeared to be distinct.

Durand's Disease.—Durand (1940) described a febrile disease in himself, which he showed to be caused by a virus. Findlay (1942), who likewise contracted the disease while working with the virus in the laboratory, suggested the name Durand's disease. The symptomatology appears to be variable. Fever lasts about 10 days, and is accompanied by headache, and sometimes by symptoms of meningeal, upper respiratory or gastric inflammation. Blood taken during the fever is infective for guinea-pigs, occasionally the urine or cerebrospinal fluid may also be shown to contain the virus. Guinea-pigs are susceptible to inoculation by practically any route. After subcutaneous injection there is an incubation period of about 6-10 days, which after one or two passages of the virus falls to 2-5 days. There is fever lasting 6-10 days, local enlargement of the lymph nodes, dyspnoea, severe loss of weight, and a leucopenia after a preliminary leucocytosis. Only about 10 per cent. of the animals die—usually after 3-4 weeks. Animals killed a week or so after the onset of the fever show emaciation, a local hæmorrhagic gelatinous œdema, great enlargement of the spleen, some degree of interstitial pneumonia, and sometimes a brownish-yellow discoloration of the liver. The virus is present in the blood and organs. Intratesticular inoculation of guinea-pigs produces an orchitis. Animals that recover from the disease are immune. Cats, dogs, and *rhesus* monkeys show some meningeal reaction after intracerebral inoculation, but most other animals develop only a latent infection. Two human patients inoculated subcutaneously by Durand for purposes of pyrotherapy became febrile in 4 days;

begin multiplication at the maximum rate at once has been attributed both to environmental factors and to the physiological state of the organisms. For example, it has been assumed that a partial pressure of carbon dioxide is essential to cell division, for, when it is prevented from accumulating by gassing with CO₂-free air or nitrogen, growth does not take place. On the other hand, the stationary and lag phases are said to be entirely eliminated by inoculation from a culture which is in the logarithmic phase of growth. Hinshelwood²⁸ has presented convincing evidence of a true and apparent lag phase, the latter resulting from the admixture in the inoculum of dead and dying cells with those capable of active proliferation. He suggests that the lag may be attributed to the time necessary for the accumulation of enzymes, diffusible coenzymes and essential intermediate compounds in the synthesis of cell substance (p. 185) to concentrations at which synthesis may occur at a maximum rate. The lag phase is of particular interest in connection with the action of drugs on bacteria (p. 152), since the bacteriostatic drugs produce an effect which is seemingly that of an indefinitely prolonged lag phase.

Hershey²⁹ has developed mathematical equations by which the latent period in multiplication and the numbers of organisms expected at any time during the phase of rapid growth may be predicted. Since only differences in the size of the cells are postulated (see below), the satisfactory agreement of experimental data with calculated values has undoubtedly more than accidental significance.

During the logarithmic growth phase the number of cells increases at a constant and practically exponential rate, for the mortality, under favorable conditions, is very low, more than 90 per cent of the cells continuing to divide. The rate of multiplication is independent of food concentration and of the effects of toxic substances over a relatively wide range, though at critical concentrations the activity of the latter increases sharply and contributes in large part to deceleration at the end of the logarithmic phase. The logarithmic growth phase, then, may be regarded as a steady state in which enzyme and substrate concentrations are maintained at such a level that the rate of synthesis of cell substance proceeds at the maximum for the strain of bacteria in that environment.

Likewise, the decreasing growth rate in the negative growth acceleration phase has been accounted for in various ways, including the rate of diffusion of oxygen into the medium, the accumulation of toxic by-products such as organic acids and ethyl alcohol, etc. It is probable that different factors are operative with different microorganisms and with the same microorganism under different conditions, and that each culture constitutes a special case.³⁰

The mechanisms operative in bacterial death, both in culture and in the presence of antiseptics, are uncertain. The survivor curves are logarithmic, i.e., the same percentage of viable organisms is dying at any particular moment. The fact that this rate may be described by a mathematical expression which likewise describes a monomolecular chemical reaction is generally held to be

²⁸ Hinshelwood *Chemical Kinetics of the Bacterial Cell*. Clarendon Press, Oxford. 1946.

experiments of Lurie (1942), who injected tubercle bacilli into normal and immune rabbits, and two days later removed specimens of tissue, from which he obtained suspensions of mononuclear phagocytes containing ingested tubercle bacilli. These were injected into the anterior chamber of the eye of normal rabbits, "immune" cells into one eye, "normal" cells into the other. After 10-14 days "normal" cells had proliferated, and the chamber contained large numbers of intracellular and extracellular tubercle bacilli; "immune" cells had not proliferated and only a few degenerate bacilli were seen, mostly intracellular. Viable counts of the contents of the anterior chamber confirmed the inference that the "immune" cells inhibited the growth of tubercle bacilli. It is not, however, clear how far the increased immunity was specific for tubercle bacilli. For example, in earlier studies Lurie (1939) showed that macrophages from tubercle-immune animals were more actively phagocytic *in vitro* than those from normal animals, but that the activity was displayed, not only towards tubercle bacilli, but towards inert particles and other bacteria. Suter (1953) recorded a similar enhancement of the ability of tissue-cultures of guinea-pig and rabbit monocytes to suppress the intracellular multiplication of tubercle bacilli, in animals immunized with B.C.G.

Perhaps the strongest argument in favour of the essential rôle of the serum antibodies in antibacterial immunity is the fact that such immunity is specific. It is true that a non-specific active immunity can sometimes be induced; but it is almost always moderate and transient (see Chapter 52). Effective and durable active immunity is usually narrowly specific; and in many cases we can identify the particular antigenic component, or components, on which it depends. There may be a specific immunity whose induction, like that of antibody immunity, is associated with the presence of a characteristic component of the bacterium, and which has nothing to do with antibody formation; we must then invoke an additional specific mechanism, in which the same antigenic components are in some way involved. There is nothing very unlikely in such an assumption, and it may well prove to be correct, but it will accord with the sound principle of economy of hypothesis, to reserve judgment pending the accumulation of further evidence.

The Dependence of Effective Antibacterial Immunity upon Particular Antibodies.

On which of the various serum antibodies does antibacterial immunity depend? This question was answered, in respect of one particular infection, long before anyone realized that it had been asked. Neufeld and Händel (1909), in their classical paper on the testing of antipneumococcal sera, first showed the existence of different serological types of pneumococci by noting that a given serum would protect a mouse against one strain of pneumococcus but not against another.

The demonstration of the presence of two separable antigenic components in the pneumococcal cell—the type-specific polysaccharide and the non-specific nucleoprotein—afforded an obvious opportunity of approaching this problem along more satisfying lines; and the results obtained were unequivocal. The antibody corresponding to the polysaccharide hapten was found to have a high protective value: the antibody corresponding to the nucleoprotein antigen had little, if any, protective effect (Avery and Morgan 1925, Avery and Neill 1925). A decisive demonstration of the protective action of the antibody acting on the specific polysaccharide, in the absence of antibodies acting on any other constituent or product of the pneumococcal cell, was made by Avery and Goebel (1931). They prepared a synthetic antigen by linking a purified polysaccharide from a culture of Type III pneumococcus to horse globulin, and with this antigen they immunized rabbits. The antisera so obtained protected mice against Type III pneumococci, but not against Type I or Type II pneumococci.

nothing more than a fortuitous coincidence, and the conclusion drawn by some workers that bacterial death is a monomolecular reaction has no basis in fact.

Morphologic Variation During Growth.³⁰ It has been observed that both the morphology and the physiological activity of bacteria differ in different phases of the growth of a culture. As growth begins to get under way, the maximum size that a given cell reaches before fission increases somewhat, and microscopic examination shows that a large proportion of the bacteria in a culture at this stage of development are appreciably larger than at other times. The cells stain evenly, and there is no evidence of granular structure even in those organisms in which metachromatic granules are most readily demonstrated. The rate of respiration per cell increases, reaching a maximum at the end of the phase of accelerating growth and declining as the culture goes into the logarithmic growth phase. The increased metabolic rate in the early growth stages is, however, more apparent than real and has been shown³¹ to be quantitatively related to cell size. The cell size declines also as the culture goes into the logarithmic growth phase, although the individual cells remain homogeneous and take stains evenly. By the time the stationary phase is reached, the bacterial cells are uniformly smaller and in cultures of spore-forming organisms, many are forming spores. As the viable bacterial count decreases the cells no longer stain uniformly but show a granular structure and involutionary forms appear. This succession of morphologic types, the embryonic or young cells, the mature forms and finally the senescent forms, has been designated *cytomorphosis*.³⁰ It is possibly analogous to a similar succession of events in the higher forms of life.

THE CHEMICAL COMPOSITION OF BACTERIA

The chemical composition of bacteria is not greatly different from that of other living material. They differ in composition from species to species, and the chemical constitution of a given species is influenced to a considerable extent by the composition of the medium upon which the organisms are grown. In consequence, a precise statement of the relative amounts of the compounds and elements of which these organisms are composed is not possible, only crude approximations may be made.

Bacterial cells contain considerable quantities of water but somewhat less than the cells of the higher plants and animals. Estimates of water content vary widely, very likely owing to the difficulty of getting accurate wet weights. Although some organisms have been reported to contain as much as 90 per cent water, most bacteria show, in the hands of careful workers, 70 to 80 per cent water. In some species of bacteria an appreciable part, 17 to 28 per cent, of this is bound water.³² The ash content, i.e., the inorganic material remaining after combustion of the cells, depends to some degree, both qualitatively and quantitatively, on the inorganic content of the medium on which the organisms are grown. The values are, therefore, subject to considerable variation, and have been given as from 2 to 14 per cent of the dry weight of the cells. The ash is largely phosphoric acid, the P_2O_5 content ranging from 10 to 45 per cent of the total ash. Undoubtedly a considerable proportion of this

³¹ Hershey and Bronfenbrenner. *Jour. Gen. Physiol.*, 1938, 21:721.

outbreak in 1917, when the attack rate was 18 per 100,000. In the epidemic of 1921 in Iceland an attack rate of 470 per 100,000 was registered. The disease resembles cerebrospinal meningitis in affecting only a small proportion of the population; though, as in meningitis, there is reason to believe that the disease is often widespread in a sub-clinical or latent form. Several workers on the basis of epidemiological or virological evidence have concluded that under endemic conditions there are something like 100 latent cases to every paralytic case (Stocks 1932, Howe 1949, Brown *et al.* 1949). In Chicago it was estimated that most children had probably been infected once by their 4th birthday and 75 per cent. twice by their 6th birthday, even though only a small proportion of them experienced the paralytic form of the disease (Casey *et al.* 1950); and that in Baltimore in 1917-8 there were probably 1,000 latent infections to every clinical case (Turner *et al.* 1950). The case-fatality rate of the declared disease varies considerably, but is usually about 10-15 per cent. It is lowest in infancy and rises with increasing age. Thus for Sweden between 1925 and 1944 Olm and Heinertz (1951) give the figures quoted in Table 178. The proportion of cases that show residual paralysis is difficult to estimate, because there is an increasing tendency among clinicians to diagnose the disease in the pre-paralytic stage. In this way a considerable number of abortive cases are included that do not develop paralysis at all. Probably not more than about 15-40 per cent. of the total cases show residual paralysis, and in many of these partial or even complete restoration of function ultimately occurs. Males are affected more often than females.

TABLE 178

CASE-FATALITY RATE OF POLIOMYELITIS IN SWEDEN 1925-44 ACCORDING TO AGE.

Age Group in Years	Paralytic cases	Case-fatality Rate %
0-	1,145	3.8
3-	2,221	5.5
7-	4,097	10.3
15-	4,551	17.2
Over 25	3,596	23.7
All ages	15,610	14.2

In the past poliomyelitis has been largely a disease of infancy and early childhood, but of late years the older age groups have been progressively more and more affected (see Burnet 1940). Thus, in the Danish outbreak of 1934 no fewer than 33.2 per cent. of the cases were in persons aged 15 years or more (Jensen 1935). There is reason to believe that the attack rate in persons infected for the first time is lowest in infancy and highest in adolescence and young adult life. In countries with a low level of sanitation the disease, mainly in the non-paralytic form, is prevalent in infants and young children. On the other hand, in countries with a high level of sanitation, little sub-clinical immunization occurs in early life, so that the average age of infection tends to be later and, as the incidence of paralysis rises with age, the paralytic form is seen more frequently (see Sabin 1947b, Nelson 1947, Burnet 1952). For example in the outbreak in Malta in 1912-3 cases were restricted mainly to children of the indigenous population and to members of the British armed services; the adult Maltese escaped almost completely (Seddon *et al.* 1945). For the same reason the incidence of the disease tends to be higher

phosphorus exists in the cell in the form of nucleic acids. Sulfur, potassium, chlorine and calcium are also present in notable amounts, together with usually smaller quantities of magnesium, iron, silicon, etc.

There is a good deal better agreement regarding the carbon content of bacteria, for most analyses give about 50 per cent of the dry weight as carbon. A part of this, of course, is present in the cell as protein, but the polysaccharide gums which make up the capsular material account for a considerable portion. Cellulose is not a common constituent of bacteria but has been identified³³ Hemicellulose is often present, and starchlike material (granulose) is found within the cells of some species.

The total nitrogen of bacterial cells varies more widely. An estimate of 8 to 15 per cent of the dry weight is in accord with the majority of analyses. A part of the nitrogen is present in the cell as protein, but very little is known of bacterial proteins. Both albumins and globulins have been isolated, the latter much more frequently. A fraction obtained by extraction by dilute alkali and called nucleoprotein has been of immunological interest and has been studied more thoroughly than other protein constituents. It appears to be a globulin combined with nucleic acid. In amino acid content the bacterial proteins do not differ materially from plant and animal proteins, and, in contrast with inorganic salt content, the amino acid composition of a given bacterium is a highly stable character and unaffected by variation in the culture medium.³⁴

A finding in keeping with the high phosphorus content of bacterial ash is the relatively large proportion of the total nitrogen that may be accounted for as nucleic acid. These organisms contain a higher proportion of nucleic acid than any other tissue except thymus, a characteristic they share with the yeasts and molds. As much as 7.1 to 11.5 per cent of the total nitrogen is purine nitrogen. Adenine, guanine, cytosine and thymine have been isolated from the tubercle bacillus, the presence of thymine and the absence of uracil suggesting the animal type of nucleic acid. Guanine has been isolated from the colon bacillus and cytosine and uracil from the cholera vibrio. Thymine is absent from the latter, suggesting in turn the plant type of nucleic acid. In addition to the nucleic acids proper (polynucleotides), their decomposition products occur in the cell, including mononucleotides, nucleosides and the free bases. The structure of bacterial nucleotides is uncertain although the predominating base is adenine. The function of adenylyl pyrophosphate as a phosphate carrier in fermentation is discussed elsewhere (p. 90).

Some bacteria contain considerable quantities of fats, lipids and waxes, *i.e.*, ether extractable material. The variation among bacteria as a group is great, analyses indicating that from 2 to 40 per cent of the dry weight may be lipid in nature. Here, however, the variation within a species is not so great, but certain species, such as the acid-fast bacteria, contain large amounts of ether extractable material. These, for the most part waxes and complex alcohols, appear to be associated with the acid-fast staining properties of these organisms.

be found in the faeces, not only of patients, but of contacts during an outbreak. Thus, Langmuir (1942) found it in the faeces of 4 out of 5 cases and of 20 out of 27 intimate contacts. The studies of Pearson and his colleagues (Pearson and Rendtorff 1945, Pearson *et al.* 1945) seem to show that the virus is restricted very largely to cases and close contacts. Thus, during an epidemic at Forth Worth, Texas, in 1943 the virus was demonstrated in the stools in 6 out of 8 households containing 27 familial contacts, in 8 out of 45 households containing 80 non-familial contacts, and in only 2 out of 127 households containing 374 non-contacts. Similarly, Kessel and Moore (1945), who examined tonsils and stools from non-contacts during an inter-epidemic period, isolated the virus from only 5 out of 136 persons studied (see also Francis and Brown 1948, Casey *et al.* 1950). Sabin and Ward (1941) were unable to find the virus in saliva. At post-mortem it can be demonstrated in the spinal cord, in parts of the intestinal tract, and sometimes in the lymph nodes (see Wenner and Paul 1947), but not in the cerebrospinal fluid or urine. For a long time it was believed to be absent from the blood, but there is increasing evidence that in man, in chimpanzees, and in *cynomolgus* monkeys it may be present during the pre-paralytic stage of the disease (see Koprowski *et al.* 1947, Horstmann 1952a, Bodian 1952a, Bodian and Passenbarger 1954).

The interpretation of these findings is difficult. They must be related to the epidemiological picture. In spite of the fact that the virus is present in the intestinal tract, is excreted in the faeces, is often present in sewage (Paul *et al.* 1940, Paul and Trask 1941, 1942, Melnick 1947, Rhodes *et al.* 1950b), and has been isolated from flies (Trask *et al.* 1943, Ward *et al.* 1945; see also Melnick and Penner 1952), the disease does not behave like a water-borne disease (see Maxcy 1943). It is true that a few milk-borne outbreaks are on record (see Aycock 1941, Goldstein *et al.* 1946), but it is well known that diseases of the respiratory tract, such as scarlet fever and diphtheria, may occasionally be carried by milk. In most outbreaks that have been carefully studied, a history of close contact with cases or with persons closely associated with cases has been established (see Burnet 1940, Aycock and Kessel 1943, Casey 1945, McFarlan *et al.* 1946, Silverthorne *et al.* 1949, Tyrrell 1951). The closeness of the association necessary is illustrated by the outbreak at Eccles, where the disease was confined for 6 weeks to one-half of the borough by a narrow canal (Sweetnam 1948). This epidemiological evidence is in general conformity with the laboratory evidence which shows, as noted above, that the virus is largely restricted to cases and close contacts of cases. It seems probable, therefore, that infection is transmitted mainly by intimate contact with the pharyngeal secretions of patients near the beginning of the illness or with the hands of patients or carriers soiled with pharyngeal or faecal material (see Dauer 1947).

The statements that infection occurs mainly by intimate association with cases, and that the virus can seldom be found except in cases and close contacts, may seem at variance with the previous statement that under endemic conditions there are estimated to be 100 latent infections to every clinical case. The discrepancy is more apparent than real. For example, at Forth Worth, Texas, 10 cases of poliomyelitis occurred in a population of 200,000. If 100 persons were infected to every clinical case, then there must have been 1,000 latent infections. Pearson and his colleagues (1945), who examined a sample of 374 persons without a history of contact, found 2 faecal carriers—a number agreeing closely with the expected finding of 1·8. It must also be remembered that the history of intimate association refers particularly to paralytic cases. It may well be that less intimate contact may give rise to infection of a degree insufficient to cause the fully developed clinical disease.

How the virus reaches the central nervous system after gaining access to the

BACTERIAL PHYSIOLOGY^{1 2}

The biochemical changes brought about through the activities of bacteria are by far the most obvious manifestations of their existence. The long-known but little understood phenomena of fermentation, putrefaction and decay, soil fertility and infectious diseases of man and lower animals are, in essence, no more than the exhibition of one or more of the many facets of the biochemical potentiality of these microorganisms. The oxidation of ammonia by the nitrifying bacteria, the decomposition of carbohydrates to alcohols and acids and the production of substances toxic to higher animals are a part of the normal activities of this heterogeneous group of living organisms. The elucidation of many of these phenomena has not only made possible a partial control of a not inconsiderable portion of man's environment but has provided an insight into the life processes of these organisms, organisms structurally so simple that morphology cannot carry us far in their study.

The term bacterial physiology, or, sometimes, bacterial metabolism, is a broad one which is generally assumed to include the entire sequence of events taking place in a bacterial culture. Since the small size of the individual bacterial cell precludes the utilization of many of the physiological techniques adapted to the multicellular, differentiated organism, the physiology of bacteria becomes, for all practical purposes, a biochemical physiology. The very magnitude of the biochemical changes brought about by these organisms tends to reinforce a belief in their relative importance, bacteria have, for example, been shown to consume forty to sixty times as much energy as man in terms of calories per gram of body nitrogen. The obvious significance of physiological activities is so readily apparent that it has tended to obscure to many the undoubted importance of the environmental factors that influence the functioning of the living cell. It is to be borne in mind, therefore, that although bacterial physiology is a branch of general cellular physiology, it must be regarded as a special case which, in many instances, goes considerably further afield into other fundamental aspects of biology than the present concept of cellular physiology is generally assumed to do.

¹ For general and more detailed discussions see: Buchanan and Fulmer: *Physiology and Biochemistry of Bacteria*, Vol. I, II and III, 1933, McGraw-Hill, New York.

Moulder, who also revised the section on autotrophic metabolism

and the animal easily becomes tired. Within a few hours ataxia develops, accompanied by tremor of the arms, legs or head. The ataxia rapidly merges into a flaccid paralysis, which extends to practically all the muscles of the body except those of the tail, jaws and diaphragm. The temperature drops to subnormal, the animal becomes weaker, and dies within 3 days after becoming prostrate (Amoss 1928). At necropsy, the lesions are similar to those in human beings, and may be briefly summarized as follows: (1) The lesions are chiefly in the grey matter of the cord; the brain is only slightly affected. (2) There is a striking perivascular sheath infiltration, and a more diffuse infiltration of the grey matter of the cord; the cells consist chiefly of lymphocytes, with a fair proportion of polymorphs and a small number of large cells with clear nuclei; plasma cells and lymphoblasts are rare. (3) There is severe degeneration of the ganglion cells of the grey matter; all stages of cellular degeneration, from a slight chromatolysis to complete neuronophagia can be seen. (4) Hemorrhages are usually present in the grey matter of the cord (McIntosh and Scarff 1928, Hurst 1929). Characteristic intranuclear inclusion bodies have been described in the nerve cells of fatal human cases, though in monkeys they are less easy to demonstrate owing to the very rapid necrosis that these cells undergo (Hurst 1931b).

Though Flexner, using *M. rhesus* monkeys, was unable to set up the disease by feeding, Kling, Levaditi and Hornus (1934) showed that *M. cynomolgus* monkeys were susceptible. The results of these workers were confirmed by Lépine and Sédallian (1939) and Vignec, Paul and Trask (1939). Chimpanzees can likewise be infected by the mouth, even after bilateral section of the olfactory tract (Howe and Bodian 1941a). Aisenberg and Grubb (1943) recorded the successful production of poliomyelitis in *rhesus* monkeys by instillation of infective material into the pulp canal of three anterior teeth. The cavities were immediately sealed to prevent escape of the virus. After 8 days all four legs were paralysed. At post-mortem, lesions were found in the Gasserian ganglions, suggestive of a direct nervous spread to the brain.

Armstrong (1939) showed that the Lansing strain of poliomyelitis virus, which had been passed through monkeys, could be transmitted by intracerebral inoculation to cotton-rats (*Sigmodon hispidus hispidus*); and Jungeblut and Sanders (1940) showed that, after becoming adapted to the cotton-rat, the strain could be passed on to white mice. The incubation period in cotton-rats is 3-8 days, in white mice 2-10 days. Paralysis of one or more legs is first observed and death occurs from respiratory failure in 24-48 hours. Recovery is uncommon (Armstrong 1941).

Properties of the Virus.—Flexner and Noguchi (1913) described the cultivation of minute globoid bodies, 0.15-0.3 μ in diameter, in an ascitic fluid rabbit kidney medium, and brought evidence to show that these bodies constituted the causative agent of the disease. The balance of evidence, however, is definitely against this conclusion (see Fairbrother 1929). Later work showed that the virus is probably much smaller—12-17 m μ (Theiler and Bauer 1934), 8-12 m μ (Elford *et al.* 1935). It resisted cultivation for a long time. In 1949, however, Enders, Weller and Robbins succeeded in growing the Lansing strain in cultures of human embryonic tissues, and in demonstrating the extremely interesting fact that growth could occur in tissue devoid of intact neurons. This work opened up a new phase in the investigation of poliomyelitis. Numerous papers by different workers appeared in rapid succession in which it was shown that culture was possible in the presence of human foreskin, human testicle, and later monkey testicle; that the Brunhilde and the Leon types could be grown as well as the Lansing type; that roller-tube cultures in which growth of the virus could be detected by its cytotoxic effect on the out-growing fibroblasts were peculiarly valuable; that colonies of the virus could be demonstrated by the formation of plaques on a layer of monkey kidney cells covered with agar, that tissue culture could be used for primary isolation of the

Morphologically bacteria are simple organisms and are often regarded as a primitive type of cell. These organisms are not simple physiologically, however; many of them oxidize glucose, for example, by mechanisms very similar to and often more complex than those used by higher animals. Others, such as the nitrifying bacteria, whose respiratory processes consist of but a single simple oxidation, synthesize all the components of protoplasm from inorganic compounds of carbon and nitrogen—a more complex process than that of joining together preformed amino acids. Since these organisms metabolize in these and other highly complex ways, it is difficult to regard them as physiologically simple. There is, however, some reason to think that bacteria are primitive cells. The view that the pathogenic organisms are degenerate forms cannot be taken to imply that the free-living forms are likewise degenerate with respect to other living cells, for such a postulate entails the assumption that the physiological capabilities of these organisms are acquired characters, and is not in keeping with current knowledge of biology. The multiplicity of reactions which bacteria are able to bring about suggests that, in these organisms, the original capabilities of protoplasm have not been lost to the extent that they have been by the differentiated cells of higher organisms. The animal body, for example, has no mechanism for the breakdown of cellulose, yet bacteria having the ability to hydrolyze this substance are universally distributed in the soil. Bacteria capable of breaking down a particular organic compound have been isolated since the early days of bacteriology by the relatively simple expedient of inoculating a highly specific medium containing the substance under consideration as the only source of energy with a complex mixture of organisms such as exist in samples of soil. It is probable that by this method a bacterium could be found which would oxidize almost any organic compound. No group of higher organisms shows such a high degree of physiological flexibility. The wide range of carbon compounds that a single bacterial species may oxidize and the multiplicity of end products of the fermentation of a single carbohydrate likewise point toward such a flexibility. The simplicity and variability of the nutritive requirements of many bacteria also suggest a physiologically primitive cell.

The physiological economy of the cell is dynamic rather than static, and life is compatible only with a state of greater or lesser, but nevertheless continuous, physiological activity. This activity may be approximately separated into two phases, the exothermic, oxidative, energy-yielding reactions, and the endothermic reduction reactions of synthesis. The former make possible a continuous, regulated supply of energy to the cell, while the latter channel this energy, or a part of it, into the synthesis of cell substance. The living cell may, therefore, be regarded as a machine for the manufacture of protoplasm, operating with a greater or lesser degree of efficiency, whose energy is supplied by the complex process of respiration. This oxidation-reduction process is not complete within itself, *i.e.*, the machine is not 100 per cent efficient, and the respiratory oxidations are not precisely balanced by the reductions of synthesis. Other substances must, therefore, be reduced to balance the excess of oxidation reactions and this is carried out through a series of reactions leading to the eventual reduction of atmospheric oxygen. The separation of the processes of respiration and synthesis cannot be complete, of course, for in many instances

intensive study of the pathogenesis of the disease likewise showed that antibodies appeared in the blood serum, probably in response to a systemic infection, during the earliest stages of the illness before paralysis had set in. Observations, mainly on antibodies to the Lansing type of virus, revealed the presence of maternally transmitted antibodies in a high proportion of new-born infants. They usually fall to a low level by the end of the 1st year of life and then rise again as the child gets older.

In Baltimore, for instance, neutralizing antibodies were found in 72 per cent. of infants under 3 months of age. This proportion fell to 10 per cent. at 1 year of age, and then rose progressively to 49 per cent. at 4 years, 72 per cent. at 5-9, 84 per cent. at 10-14, and 89 per cent. over 15 years of age (Turner *et al* 1950). Similar observations were made in Cairo, though the rise was more rapid, 90 per cent. of sera containing antibodies by the age of four (Goldblum and Melnick 1952).

Generally speaking, the more primitive the sanitary conditions, the earlier and more widespread is the development of antibodies. Thus Hammon, Sather and Paul (1951), from children in different parts of the world, found antibodies first in the Pacific Islands, slightly later in Japan, then in the United States of America, and latest of all in California. As a rule antibodies develop as the result of a latent infection, and appear most often during the epidemic season. Turner and his colleagues (1950) in Baltimore made repeated tests on 272 children whose serum was free from antibodies at the first examination. Over a 2-year period sera from 51 of these children became positive, indicating a mean annual infection rate of 20.4 per cent. Of 201 initially negative children observed over the summer months approximately 20 per cent. became positive, whereas of 224 children observed through two winters less than 0.5 per cent. became positive. None of the children in whom antibodies developed showed any clinical illness suggestive of poliomyelitis. There is evidence that neutralizing antibodies persist indefinitely in the serum, though complement-fixing antibodies are transient and are indicative of recent infection (Goldblum and Melnick 1952).

Paul, Riordan and Melnick (1951), for example, studying the distribution of neutralizing antibody against different types of poliomyelitis virus in the North Alaskan Eskimos, found neutralizing antibodies of the Lansing type in persons over 20 years of age, and of the Brunhilde and Leon types in persons of over 30 and 40 years of age respectively. They concluded that the presence of these different antibodies was probably associated with epidemics of poliomyelitis in the years 1905, 1915, and 1930, each being due to a different type of virus.

Most of the evidence suggests that neutralizing antibodies protect specifically against clinical disease caused by the homologous type of virus. Whether they protect also against latent infection is more questionable. Hammon (1949), whose review on immunity in poliomyelitis repays careful study, quotes several observations in which the adult members of a family in which a single case of poliomyelitis had occurred became transient throat or intestinal carriers of the virus in spite of antibodies in their serum. On the other hand, Brown and Ainslie (1951) found an inverse relationship in family outbreaks between the presence of neutralizing antibodies and the frequency with which virus could be isolated from the faeces. On the whole the evidence suggests that a lasting type-specific immunity develops

the products of the respiratory process are assimilated by the cell and utilized for synthetic purposes, in fact in very many instances a preliminary decomposition is necessary before assimilation can occur.

From the point of view of chemical kinetics it is tempting to regard the living cell as a macromolecular polyfunctional free radical system which is partially stable because of spatial separation of the free valencies in the organized cell structure that would otherwise saturate one another in a homogeneous phase. The structural protection is only partial, however, and decay of the system is counteracted by its participation in chain reactions accompanied by large decreases in free energy, i.e., free valencies are maintained by the respiratory reactions.

A reasonable amount of information is available with respect to respiration, regarding both the catalysis of the reactions and the intermediary metabolism of the substrates, i.e., the successive reactions involved. On the other hand, the mechanisms of synthesis of the components of protoplasm are almost completely unknown, not only for the bacteria but for other organisms as well. Elucidation of the nutritive requirements of bacteria may, perhaps, be regarded as definition of the precursors of protoplasm in the catalytic system that is the microorganism under consideration; it may equally well be regarded as definition of the limits of the synthetic abilities of the organism.

RESPIRATION³

Lavoisier's classic experiments on animal respiration performed at the close of the eighteenth century led to the definition of respiration as the utilization of oxygen and the production of carbon dioxide and water, and the presence of molecular oxygen was considered to be absolutely essential for life. However, the meaning of the term respiration was gradually broadened after Pasteur discovered in 1861 that many bacteria can grow and thrive in the complete absence of oxygen. Perhaps the most general definition one can give is that of respiration as the sum total of the chemical reactions carried out by the living cell which result in the liberation of energy.

Of these energy-yielding reactions by far the most important are those of oxidation-reduction. In an oxidation-reduction reaction, one substance is oxidized and one substance is reduced. According to Clark⁴ and to Michaelis,⁵ the oxidized substance loses electrons and the reduced substance gains electrons. If, in the respiration of a living cell, molecular oxygen is the ultimate oxidizing agent, and thus the ultimate acceptor of electrons, the respiration is said to be aerobic. If another substance, not oxygen, is the final electron acceptor, the respiration is said to be anaerobic. The oxidation-reduction reactions of respiration have two functions: they transform nutrient material into substances needed for the maintenance and growth of the cell, and they liberate energy from the nutrient material for use in the cellular economy.

³ For a general discussion of respiration, see Green *Mechanisms of Biological Oxidation*, Cambridge University Press, Cambridge, 1940, and *A Symposium on Respiratory Enzymes*, University of Wisconsin Press, Madison, 1942. The general subject of bacterial respiration has been discussed by Werkman: *Bact. Rev.*, 1939, 3:187.

⁴ Clark, *Public Health Repts.*, 1923, 38:443. This and nine additional papers on oxidation-reduction studies are contained in *Hygienic Laboratory Bulletin* No. 151, 1928.

⁵ Michaelis and Schubert, *Chem. Rev.*, 1938, 22:437.

chemoprophylaxis of the disease. These workers brought evidence to suggest that the application to the nasal mucosa of a 2-4 per cent. solution of alum, or better of a 0.32-0.64 per cent. solution of picric acid, was capable of increasing the local resistance of monkeys to intranasal infection with the virus. Schultz and Gebhardt (1937) found that a 0.5 per cent. solution of zinc sulphate was even more effective. Field trials, however, on human beings in the United States and Canada have been (Tisdall *et al.* 1937, Schultz and Gebhardt 1942). Not

prophylactic effect, but they may do considerable local damage by causing extensive coagulation necrosis of the olfactory epithelium. Moreover, since there is serious doubt as to whether infection in man occurs by the nose, the rationale of this form of prophylaxis rests on very slender grounds. The method has now been generally abandoned.

A curious phenomenon, which may or may not prove to be of value in practice, was observed by Sanders and his colleagues (1953), who found that the subcutaneous injection of detoxified cobra venom (from *Naja flava*) 24 hours after intracerebral inoculation of monkeys with poliomyelitis virus delayed the onset of the disease.

Vaccination.—Since neither eradication of the source of infection nor successful interference with the transmission of infection appears to be practicable, it is logical to attempt to control the disease by raising the resistance of the host. Early attempts to vaccinate children were made by Kolmer and his colleagues (Kolmer and Rule 1934a, b, Kolmer 1935, Kolmer *et al.* 1935), using a 4 per cent. suspension of infected monkey cord in 1 per cent. sodium ricinoleate. The virus, though living, was said to be attenuated. Brodie (1934b) and Brodie and Park (1935) recommended a vaccine in which the virus had been inactivated by exposure to 0.1 per cent. formol at 37° C for 8-12 hours. Both of these vaccines were tried on a small scale in the United States. The demonstration, however, by Olitsky and Cox (1936) that Kolmer's vaccine might occasionally give rise to poliomyelitis in monkeys, and the even more serious development of the disease in children, occurring apparently as the result of prophylactic vaccination (Leake 1935), led to the discontinuance of their use.

These unfavourable results set back the clock for the time being, but investigation was renewed and enormously stimulated when evidence accumulated to show the probable occurrence of an early viraemic stage in the disease, and when the way of growing the three different types of virus in tissue culture was discovered. Morgan, Howe and Bodian (1947) brought evidence to show that monkeys could be protected against intracerebral inoculation by intramuscular injections of a vaccine inactivated by formalin or ultraviolet irradiation, and that the degree of resistance was related to the height of the antibody content of the serum. Morgan (1949) obtained evidence that immunity of monkeys following vaccination was probably type-specific. Later, Melnick and Ledinko (1951) found that, with *cynomolgus* monkeys infected by the mouth with living virus of the Lansing type, animals that failed to develop paralysis were subsequently resistant to infection by the intranasal or intracerebral route and that the degree of resistance was associated with the antibody content of the serum. In 1953 Salk reported the first major trial on children. The vaccines he used were prepared from the three different types of virus grown in roller-tube cultures of monkey kidney. Inactivation was carried out by exposure to 0.4 per cent. formalin at 1° C. over a period of several days, the action of the formalin being finally neutralized by sodium bisulphite. The product was stored in the refrigerator. No vaccine was used till it was shown to be innocuous when injected intracerebrally into monkeys. Aqueous vaccines injected intradermally into human subjects were found to stimulate the

Morphologically bacteria are simple organisms and are often regarded as a primitive type of cell. These organisms are not simple physiologically, however, many of them oxidize glucose, for example, by mechanisms very similar to and often more complex than those used by higher animals. Others, such as the nitrifying bacteria, whose respiratory processes consist of but a single simple oxidation, synthesize all the components of protoplasm from inorganic compounds of carbon and nitrogen—a more complex process than that of joining together preformed amino acids. Since these organisms metabolize in these and other highly complex ways, it is difficult to regard them as physiologically simple. There is, however, some reason to think that bacteria are primitive cells. The view that the pathogenic organisms are degenerate forms cannot be taken to imply that the free-living forms are likewise degenerate with respect to other living cells, for such a postulate entails the assumption that the physiological capabilities of these organisms are acquired characters, and is not in keeping with current knowledge of biology. The multiplicity of reactions which bacteria are able to bring about suggests that, in these organisms, the original capabilities of protoplasm have not been lost to the extent that they have been by the differentiated cells of higher organisms. The animal body, for example, has no mechanism for the breakdown of cellulose, yet bacteria having the ability to hydrolyze this substance are universally distributed in the soil. Bacteria capable of breaking down a particular organic compound have been isolated since the early days of bacteriology by the relatively simple expedient of inoculating a highly specific medium containing the substance under consideration as the only source of energy with a complex mixture of organisms such as exist in samples of soil. It is probable that by this method a bacterium could be found which would oxidize almost any organic compound. No group of higher organisms shows such a high degree of physiological flexibility. The wide range of carbon compounds that a single bacterial species may oxidize and the multiplicity of end products of the fermentation of a single carbohydrate likewise point toward such a flexibility. The simplicity and variability of the nutritive requirements of many bacteria also suggest a physiologically primitive cell.

The physiological economy of the cell is dynamic rather than static, and life is compatible only with a state of greater or lesser, but nevertheless continuous, physiological activity. This activity may be approximately separated into two phases, the exothermic, oxidative, energy-yielding reactions, and the endothermic reduction reactions of synthesis. The former make possible a continuous, regulated supply of energy to the cell, while the latter channel this energy, or a part of it, into the synthesis of cell substance. The living cell may, therefore, be regarded as a machine for the manufacture of protoplasm, operating with a greater or lesser degree of efficiency, whose energy is supplied by the complex process of respiration. This oxidation-reduction process is not complete within itself, *i.e.*, the machine is not 100 per cent efficient, and the respiratory oxidations are not precisely balanced by the reductions of synthesis. Other substances must, therefore, be reduced to balance the excess of oxidation reactions and this is carried out through a series of reactions leading to the eventual reduction of atmospheric oxygen. The separation of the processes of respiration and synthesis cannot be complete, of course, for in many instances

Infections due to the Coxsackie Group of Viruses

In 1918 Dalldorf and Sickles isolated from the stools of 2 children suffering from poliomyelitis a virus that induced paralysis in suckling mice and hamsters but had no effect on *rhesus* monkeys. Paralysis followed intracerebral, intraperitoneal, or intramuscular injection and was characterized by widespread degenerative lesions of the skeletal muscles with little apparent effect on the central nervous system. The following year Dalldorf (1919) reported the isolation of 10 further strains and noted that they were not all antigenically alike. Though a rise in the neutralizing antibody content of the serum was observed in some of the patients, the part played by the virus in the causation of the clinical disease remained doubtful. Widespread interest was aroused by the descriptions of the new virus and it was not long before numerous other strains were isolated in the United States (Curnen *et al.* 1919, Melnick *et al.* 1950, Huebner *et al.* 1950, Weller *et al.* 1950), in Canada (Rhodes *et al.* 1950a), in Great Britain (Findlay and Howard 1950), and in other countries (see Vivell and Gudeke 1952). From the town in New York State in which it was first isolated, it was called the Coxsackie virus.

The virus is found mainly in faeces and sewage, less often in the throat. It has also been isolated from flies. It is spherical in shape. Estimates of its diameter range from 6 $m\mu$ to 37 $m\mu$ according to the strain examined and the method used. It is difficult to propagate in the laboratory, and only occasional strains have been adapted to growth in the fertile egg or in tissue culture. In mouse brain suspension and in faeces it remains stable at -70° C. for several months. It is killed by heat at 55° C. within 30 minutes. It survives in 50 per cent. glycerol for at least 5 months, but is inactivated at room temperature by 0.25 per cent. formalin (Dalldorf *et al.* 1919). It is destroyed by 0.6 p.p.m. of chlorine at pH 7.0 in about 10 minutes (Clarke and Kabler 1951). By complement-fixation and neutralization tests at least 16 different antigenic types can be distinguished (see Contreras *et al.* 1952).

According to the lesions they give rise to in suckling mice the different antigenic types are classified into two groups—A and B. Strains of Group A injected intracerebrally into suckling mice lead to generalized weakness in 2–3 days followed by death or paralysis the following day. At post-mortem the skeletal muscles are white and firm in appearance, and microscopically show hyaline degeneration of the kind described by Zenker. Strains of Group B, on the other hand, cause either spasticity or paralysis with delayed death. The irregular tonic contractions of the muscles may give rise to torsion of the body resulting in what is sometimes known as the *rolling disease*. At post-mortem there are found focal myositis, softening of the brain, and necrosis of the subcutaneous and visceral fat, some strains may cause hepatitis or massive necrosis of the acinar tissue in the pancreas (Dalldorf 1950, Pappenheimer *et al.* 1951). The distinction between the two groups is not always clear. There is a certain amount of overlapping, and occasional strains resemble viruses of the encephalomyocarditis group (see p. 2155). The distinction between them may be aided by the circumstance that in their growth in tissue cultures the viruses of Groups A and B are said to differ in their nutritional requirements (Weller *et al.* 1953). A third group, called Group C, was described by Stanley, Dorman and Ponsford (1953) in association with an outbreak of encephalitis at Sydney. It differed from Groups A and B in various respects, notably its lack of virulence for mice more than 24 hours old and its failure to affect the skeletal muscles.

Bacterial Physiology

the products of the respiratory process are assimilated by the cell and utilized for synthetic purposes, in fact in very many instances a preliminary decomposition is necessary before assimilation can occur.

From the point of view of chemical kinetics it is tempting to regard the living cell as a macromolecular polyfunctional free radical system which is partially stable because of spatial separation of the free valencies in the organized cell structure that would otherwise saturate one another in a homogeneous phase. The structural protection is only partial, however, and decay of the system is counteracted by its participation in chain reactions accompanied by large decreases in free energy, i.e., free valencies are maintained by the respiratory reactions.

A reasonable amount of information is available with respect to respiration, regarding both the catalysis of the reactions and the intermediary metabolism of the substrates, i.e., the successive reactions involved. On the other hand, the mechanisms of synthesis of the components of protoplasm are almost completely unknown, not only for the bacteria but for other organisms as well. Elucidation of the nutritive requirements of bacteria may, perhaps, be regarded as definition of the precursors of protoplasm in the catalytic system that is the microorganism under consideration, it may equally well be regarded as definition of the limits of the synthetic abilities of the organism.

RESPIRATION¹

Lavoisier's classic experiments on animal respiration performed at the close of the eighteenth century led to the definition of respiration as the utilization of oxygen and the production of carbon dioxide and water, and the presence of molecular oxygen was considered to be absolutely essential for life. However, the meaning of the term respiration was gradually broadened after Pasteur discovered in 1861 that many bacteria can grow and thrive in the complete absence of oxygen. Perhaps the most general definition one can give is that of respiration as the sum total of the chemical reactions carried out by the living cell which result in the liberation of energy.

Of these energy-yielding reactions by far the most important are those of oxidation-reduction. In an oxidation-reduction reaction, one substance is oxidized and one substance is reduced. According to Clark² and to Michaelis,³ the oxidized substance loses electrons and the reduced substance gains electrons. If, in the respiration of a living cell, molecular oxygen is the ultimate oxidizing agent, and thus the ultimate acceptor of electrons, the respiration is said to be aerobic. If another substance, not oxygen, is the final electron acceptor, the respiration is said to be anaerobic. The oxidation-reduction reactions of respiration have two functions: they transform nutrient material into substances needed for the maintenance and growth of the cell, and they liberate energy from the nutrient material for use in the cellular economy.

¹ For a general discussion of respiration, see Green *Mechanisms of Biological Oxidation*, Cambridge University Press, Cambridge, 1940; and *A Symposium on Respiratory Enzymes*, University of Wisconsin Press, Madison, 1942. The general subject of bacterial respiration has been discussed by Werkman, *Bact. Rev.*, 1939, 3:187.

lasting 2-5 days or so have been reported in children and adults during the summer months. The chief clinical features are usually fever, headache, sore throat, and myalgic pains in the back, neck, abdomen, and limbs. There is, however, considerable variation in the symptomatology, and a tendency to merge into the picture of aseptic meningitis. In some of these outbreaks Cocksackie virus has been demonstrated in the stools of a high proportion of the patients examined and neutralizing antibodies have appeared in the serum during the course of the disease (Melnick *et al.* 1950, Kenyon *et al.* 1952, Wood *et al.* 1952).

Bornholm disease : epidemic myalgia : epidemic pleurodynia.—This disease, which has been observed in various parts of the world, was described by the Danish physician Sylvest, who studied an outbreak in Bornholm in 1930 and published a monograph on it in 1931. It is characterized by fever, acute pain, usually of sudden onset, affecting the chest, upper abdomen, or lower region of the back on one or both sides, often headache, little or no constitutional disturbance, an absence of catarrh, and a tendency to relapse. The pain is paroxysmal and lasts for a day or more. The muscles are tender on pressure. Relapses are common at intervals of 2 or 3 days, or after a longer period. Orchitis may be seen as a complication. Fatal cases are rare. The incubation period is 2-4 days. The disease occurs in epidemic form, usually in the late summer. Infection probably spreads by contact and is caused by the B type.

A similar disease, differing in not affecting the respiratory muscles of the chest and abdomen and in being comparatively afebrile, was described by Beeson and Scott (1942) under the term *epidemic myalgia of the neck and shoulders*.

In several outbreaks of the Bornholm type Cocksackie virus has been isolated from the throat or faeces of a considerable proportion of the patients examined, and the development of antibodies demonstrated in the blood (Weller *et al.* 1950, Findlay and Howard 1950, Lazarus *et al.* 1952, Bury and Tobin 1952, Gabinus *et al.* 1952). In 2 cases studied by Lépine, Desse and Sautter (1952) lesions were demonstrated in the muscles similar to those found in suckling mice, and the Cocksackie virus was isolated from both the muscles and the faeces.

It may be added that in *diagnosis* of the Cocksackie group of infections great care must be exercised in the interpretation of the serological reactions. Antibodies to various types of the virus are often present in normal persons. Complement-fixing antibodies are not strictly type-specific and the titre to heterologous types may be higher than that to the homologous type (Kraft and Melnick 1952). For fuller information on this virus and the diseases it causes the reader may consult the reviews by Melnick and Curnen (1952), Vivell and Gadeke (1952), and Tobin (1953).

RABIES

Rabies is a disease of animals affecting particularly dogs, cats and carnivorous wild animals; herbivora are less frequently attacked. The disease is transmissible to human beings by the bites of rabid animals, notably dogs, cats, wolves, and jackals. The incubation period varies according to the age of the animal, the situation of the bite, and the severity and nature of the bite. Generally speaking, it varies in animals from 2 to 8 weeks, and in human beings from 6 to 8 weeks; it tends to be shorter in young animals and children, and after severe lacerated or

Oxidation-Reduction Potential.⁶ A simple example of an oxidation-reduction reaction is the reaction between ferric iron and cuprous copper.

When the oxidation-reduction involves organic compounds, as in almost all biological oxidations, oxidation often results in transfer of hydrogen atoms as well as of electrons, and biological oxidation is often referred to as hydrogen transport. The oxidation of ethanol to acetaldehyde, for example, is accompanied by transfer of hydrogen as well as of electrons.

It is obvious that any substance capable of entering into oxidation-reduction reactions must exist in two forms—an oxidized form and a reduced form. These two forms constitute a reversible oxidation-reduction system.

Oxidized form Reduced form

The oxidizing power of an oxidation-reduction system is a function of its ability to donate electrons to another system and may be quantitatively expressed as the oxidation-reduction potential of the system.

The oxidation-reduction potential has the dimensions of volts and may be measured in a suitable electrical circuit. The oxidation-reduction potential, E_h , is defined by the general electrode equation,

$$E_h = E_o - \frac{RT}{nF} \ln \frac{[\text{Red}]}{[\text{Ox}]}$$

in which E_h and E_o are measured in volts, R is the gas constant, T is the absolute temperature, F is the faraday, and n is the number of electrons transferred in the oxidation-reduction reaction. The observed oxidation-reduction potential, E_h , is a function of E_o , a constant for the system, and the ratio of the molar concentrations of the oxidized and reduced forms. When

$$\frac{[\text{Red}]}{[\text{Ox}]} = 1, \quad \text{then} \quad E_h = E_o$$

and this relationship serves to define the constant, E_o . Each oxidation reduction system has a characteristic E_o value. The potential of the system,

at pH 0 and 1 atmosphere of hydrogen is arbitrarily assumed to be 0, and all other oxidation-reduction potentials are expressed in relation to the potential of this system, the normal hydrogen electrode.

If either or both the oxidized or reduced forms of a system are ionized, changes in pH will alter the potential of the system by disturbing ionic equilibria. Because of this effect the pH must be specified for each observed value of E_h , or else the value is meaningless. The E_o of a system represents the potential at which the system is half-oxidized at pH 0, and another symbol, E_o' , is used to represent the potential of a half-oxidized system at a specified pH.

⁶ For a general discussion appropriate here, see Hewitt: *Oxidation-Reduction Potentials in Bacteriology and Biochemistry*. 4th ed. London County Council. P. S. King & Son, Ltd., London. 1936.

injected subcutaneously, the street virus alone proves virulent. It would appear that by passage through the rabbit's brain, the fixed virus has acquired a strong neurotropic affinity, which enables it to give rise to rabies in 7 days after subdural injection, but which usually renders it avirulent on subcutaneous inoculation. The street virus, on the other hand, takes about 14 days to produce rabies on subdural inoculation, and usually proves virulent when introduced subcutaneously. Fixed viruses can likewise be produced by passage through guinea-pigs, dogs, hens, and monkeys (Pasteur *et al.* 1884). Both street viruses, and the fixed viruses derived from them, show considerable variability in their virulence for animals; some rarely produce infection when inoculated subcutaneously, others always do so (Marie *et al.* 1927). Pasteur (Pasteur *et al.* 1884) found that by passage through the brain of monkeys, the virus diminished in virulence for dogs, though when passed through rabbits or guinea-pigs it uniformly increased in virulence.

The virus is present in the saliva of rabid animals, and has sometimes been demonstrated in it 4 days before the onset of clinical symptoms. It is also found in the central nervous system, the peripheral nerves, and in the salivary glands, less regularly in the cerebrospinal fluid. Occasionally it may be demonstrated in the blood and the internal organs (Pasteur *et al.* 1884, Remlinger and Bailly 1931, 1932). The virus passes along the nerves from the local injury, and reaches the central nervous system; this is shown by the fact that (1) the animal may live after resection of experimentally infected nerves; (2) the resected nerves are themselves infective; (3) the portion of the spinal cord in connection with the infected nerve becomes infective before other parts of the central nervous system (di Vestea and Zagari 1889, Marie *et al.* 1927). According to Nicolau and Galloway (1928), the virus, when introduced into the brain, may spread centrifugally, and be found in such nerves as the brachial and sciatic; the passage of the virus along the nerves sets up an interstitial neuritis. It has been suggested that the salivary glands owe their infectivity to the presence in them of neurones, which may occur as single cells or as ganglionic aggregations, and which are situated just under the epithelium; if the epithelium is abraded, the virus is set free from the neurones, and infects the saliva (Manouélian and Viala 1927, 1928; for references see McKendrick 1928).

Properties of the Virus.—The rabies virus can pass through Berkefeld candles. Galloway and Elford (1936), from filtration experiments carried out with gradocol membranes on a strain of fixed virus, estimate its size as 100–150 μ . This agrees with the value obtained for another strain of fixed virus by Yaoi, Kanazawa and Sato (1936). The virus can be grown in tissue cultures containing embryo brain and human or monkey serum (Kanazawa 1936, Webster and Clow 1937). It can also be cultivated on the chorio-allantoic membrane of the developing chick embryo, provided 5- or 6-day embryos are used (Kligler and Bernkopf 1941). Cultivated strains tend to lose their virulence fairly rapidly. According to Sankaran, Iyengar and Beer (1934), the virus can be separated from infected rabbit brain by electrophoresis. It is not very resistant. It is destroyed by exposure to a temperature of 60° C. for 30 minutes. Slow drying gradually renders it inert, but if rapidly dried it may retain its infectivity for months. The fixed virus is very sensitive to the photodynamic action of methylene blue (Shortt and Brooks 1934, Galloway 1934) and to irradiation with ultraviolet light (Sankaran and Beer 1935). It is readily killed by bile. Little is known about its antigenic structure, but most strains seem to resemble each other fairly closely (Remlinger

Systems with relatively high E_0 's have strong tendencies to accept electrons and are good oxidizing agents. Systems with relatively low E_0 's have strong tendencies to donate electrons and are good reducing agents. The oxidized form of any system may oxidize (accept electrons from) the reduced form of any system with sufficiently lower E_0 . Such reactions always proceed with the liberation of energy (decrease in the free energy of the system). That is, the energy contained in the products of the reaction is always less than that contained in the reactants.

Application to Biological Systems. The foregoing treatment of oxidation-reduction potential applies only to completely reversible systems. A number of biological systems are reversible and electromotively active and therefore susceptible to such analysis. This group includes the cytochromes and cytochrome oxidase, the flavoproteins, and a number of naturally occurring pigments. A second group is made up of the sluggish systems, so called because of their sluggish behavior at the electrode, which are regarded as only partially electromotively active. The pyridine nucleotides and the sulfhydryl compounds such as glutathione and cysteine belong to this group, and the measurement of their oxidation-reduction potentials is difficult and generally unsatisfactory. Lastly, there are those sluggish systems that develop potentials only in the presence of specific enzymes, the enzymatic oxidation-reduction systems. There are many of these, including succinic acid-fumaric acid, lactic acid-pyruvic acid, alcohol-acetaldehyde, and others.

Since many of the oxidation-reduction systems in the living cell fall into this last group, it is very difficult to interpret potentials produced during active cellular metabolism when a number of systems must be functioning simultaneously. As a matter of fact, it is doubtful that the reducing intensities developed should be termed "oxidation-reduction potentials" at all. Probably reduction potential or reducing intensity is the most satisfactory term for potentials developed by the actively metabolizing intact cell. The accompanying table gives the oxidation-reduction potentials of some important biological systems.

OXIDATION-REDUCTION POTENTIALS OF BIOLOGICALLY IMPORTANT SYSTEMS AT pH 7

Oxidation-Reduction System		E_0 in volts	T C*
Oxidized Form	Reduced Form		
O_2	H_2O	0.81	25
Ferro-cytochrome oxidase	Ferro-cytochrome oxidase	?	
Ferro-cytochrome <i>a</i>	Ferro-cytochrome <i>a</i>	0.29	25
Ferro-cytochrome <i>c</i>	Ferro-cytochrome <i>c</i>	0.26	25
Ferro-cytochrome <i>b</i>	Ferro-cytochrome <i>b</i>	-0.04	25
NO_3^-	NO_2^-	0.05	30
Methylene blue	Reduced methylene blue	0.01	30
Pyocyanine	Reduced pyocyanine	-0.03	30
Fumaric acid	Succinic acid	-0.03	25
Flavoprotein	Reduced flavoprotein	-0.06	38
Oxalacetic acid	Malic acid	-0.10	37
Phthiocol	Reduced phthiocol	-0.17	30
Pyruvic acid	Lactic acid	-0.18	35
Acetaldehyde	Ethanol	-0.19	30
Diphosphopyridine nucleotide	Reduced diphosphopyridine nucleotide	-0.29	30
H^+	H_2	-0.41	25

the mouse passage method (Webster and Dawson 1935), affords the most rapid means of determining the presence of infection in a suspected animal.

Diagnosis.—In attempting to reach a diagnosis of rabies in a human being before the disease has declared itself, it is important if possible, not to kill the animal responsible for the bite, but to keep it in safe captivity for a few days to see whether the typical symptoms of the disease develop. If it is killed before the onset of the paralytic stage, no Negri bodies may be found in the brain. Once the animal is paralysed, it should be killed, and the brain examined by a rapid section method for Negri corpuscles, or preferably by impression smears stained by Sellers' method (see Johnson 1952). Negri corpuscles are demonstrable in only about 90 per cent. of animals and 70 per cent. of human patients that have died of rabies. Resort should therefore be had to the mouse inoculation test described by Webster and Dawson (1935) if the brain of a suspected animal fails to reveal these bodies microscopically. The mouse test should also be used when the animal has been prematurely destroyed or the brain improperly preserved.

Webster (1936) recommends that sterile pieces of Ammon's horn of the suspected animal should be made into a 5 or 10 per cent. suspension with distilled water, and that 0.03 ml. should be inoculated intracerebrally and 0.25 ml. intramuscularly into each of 6 mice belonging to the specially susceptible Swiss breed. One animal should be killed on the 5th, 6th, and 7th days respectively, and its brain examined for Negri bodies. The remaining three are observed for 4 weeks for signs of rabies. In practice, a negative diagnosis may usually be given in 3 weeks (Thomas 1939). The advantage of the mouse over the rabbit is that it is more susceptible, it is easier to inoculate intracerebrally, and it develops rabies, on the average, a week earlier.

If the brain of a suspected animal cannot be examined fresh, it should be packed in ice before transmission to the laboratory; or, alternatively, half of it may be sent in 10 per cent. formalin for section and half in 50 per cent. glycerol for inoculation.

An attempt may be made to isolate the virus from the saliva of man or animals, particularly in cases of the paralytic type, which often present considerable difficulty in diagnosis. For this purpose intramuscular injection of the Syrian hamster is to be recommended, as this animal is very susceptible to street virus given peripherally (Koprowski 1949). Complement-fixation and neutralization tests may be used to demonstrate a rise in the patient's serum antibodies and are recommended as a routine procedure by Johnson (1949). In practice, however, they are seldom of value, nor are they suitable for diagnosis of the disease in animals (Terkel 1948).

Prophylactic Treatment of Rabies.

After infliction of the bite, an attempt should be made to destroy as much of the virus in the wound as possible. For this purpose, treatment with a 20 per cent. solution of soft soap is said to be as effective as cauterization with fuming nitric acid (Shaughnessy and Zichis 1943). Tincture of iodine is also useful, if applied within 30 minutes.

Vaccination.—Rabies is a fatal disease, and once symptoms have declared themselves, treatment is of no avail. But the disease is characterized by a long incubation period; and it was Pasteur (1885) who realized the possibility of using this period for carrying out specific vaccine treatment. Pasteur found that the spinal cords of rabbits dying of experimental rabies gradually lost their virulence when dried in air over KOH. By inoculating dogs with cords dried for varying

Reduction Potentials of Bacteria. The development of reducing properties by bacteria is associated with equivalent electrometric and colorimetric changes, indicating that the predominant system or systems are reversible. The potentials may be developed by bacterial suspensions in the presence of added substrate, or during growth in culture; the latter state has been by far the more commonly studied.

Fig. 17. Diagrammatic representation of the method used in the measurement of reduction potentials developed in bacterial cultures. The culture vessel should contain duplicate electrodes and an additional opening for inoculation, removal of samples, etc.

Measurements of the reducing intensity are made electrometrically, using bright platinum or gold plated platinum electrodes, as the use of indicator dyes which change color with oxidation or reduction has been unsatisfactory. A satisfactory arrangement is illustrated in Fig. 17 in diagrammatic form. The bacterial culture is a half cell, and the standard half cell is a saturated calomel cell. The whole is immersed in a constant temperature bath. With buffered broth as the culture medium, the pH is maintained without significant variation. The reducing capacity of the bacterial culture is very low, *i.e.*, it is poorly poised (analogous to poorly buffered with respect to changes in pH), and if appreciable amounts of current are passed through the system in the measurement of the potential, the electrodes polarize, making readings impossible. It is necessary, therefore, to insert a high resistance in series with the cell, so that only a very small current passes through the culture. The calculation of the potential is simple:

$$E_h = E_{obs} + E_{std}$$

where E_{obs} is the observed potential and E_{std} is the potential of the standard half cell. Measurement of the developing potential may be made at intervals to give a time-potential curve.

The potential of a freshly-prepared sterile culture medium often shows a slight, gradual negative drift. When inoculated with bacteria, however, the

time for them to appear is between the 11th and 30th days after the bite, that is to say usually before the onset of rabies in untreated persons. The severer forms of paralysis prove fatal in about 25 per cent. of cases. What they are due to is not known with certainty, but there is reason to believe that, like the encephalitis following some of the infectious diseases, they are allergic in nature (see Remlinger 1927, Hurst 1952).

The average case fatality in treated patients in McKendrick's series varied over a number of years between 0.23 and 0.49 per cent.

How, it may be asked, can a dead vaccine, inoculated into the patient after living virulent virus has gained access to the body, afford any protection against the disease? The virus is known to be neurotropic, and almost certainly finds its way to the brain and cord by way of the nerves. If an attenuated virus was inoculated in enormous quantities very soon after the bite, it is conceivable that some of it might reach the susceptible nerve cells and block the entry of the virulent virus. But how can this happen with a dead vaccine, unless transport along the neurones is purely mechanical? Yet, from McKendrick's figures a dead vaccine appears to be just as efficacious as a living attenuated virus. The only answer to this question is to assume that the vaccine reaches the central nervous system by the blood stream and there causes the necessary interference. Surprisingly enough, there seems to be no advantage in early treatment; the fatality of those treated 0-4, 5-7, or 8-14 days after the bite was, among Europeans, 0.19, 0.10 and 0.06 per cent. respectively. Animal experiments do not increase our confidence in vaccination. The observations of Shortt and of Covell and their colleagues in India (Shortt *et al.* 1934, 1935, Covell *et al.* 1936), and of other workers (see Webster 1939*b*) seem to show that (1) no vaccine can protect an animal *after* exposure to infection by rabies virus, (2) vaccine given *before* exposure to infection is effective only provided (a) it is given repeatedly and in large doses, totalling at least 1 per cent. of the body weight, and (b) the test dose is given subcutaneously, intramuscularly, or by some other route than the intracerebral.

Considerations such as these have led many workers to question the value of the vaccine treatment of rabies. Ever since Pasteur recorded his apparently brilliant successes, persons who have been bitten by rabid animals have been given treatment as a matter of course. In such a disease it would be unjustifiable to withhold it so long as there was any reason to believe that it might confer some degree of protection. The result has been that there are no adequate control figures available. A high proportion of persons treated have probably not been bitten by rabid animals, and, of those who have, probably not more than a quarter would have developed rabies anyway. The figures of the Pasteur Institutes therefore throw little light on the main question at issue.

Progress in the past has been hampered by the absence of a satisfactory technique for standardizing anti-rabic vaccines. Webster (1939*a*) filled this need by introducing a mouse inoculation test. By its use he found that commercial vaccines of the killed type were often devoid of protective action or were effective only in doses greater than those recommended by the manufacturers (see also Wyckoff and Beck 1940). Webster's technique was modified by Habel (1940*a*), whose mouse potency test is the one now generally adopted. Comparative titrations of different vaccines revealed considerable variations in the antigenic potency of the strains used to prepare commercial vaccines (Habel 1940*b*), and the results of the potency tests with any one vaccine varied according to the strain of infecting virus

potential falls rapidly during the early hours of incubation. Thereafter, it differs somewhat with the type of bacterium. In the case of the obligate anaerobes (see Fig. 18) it reaches and maintains a very low level, sometimes approaching or reaching the level of hydrogen overvoltage, i.e., more negative than the normal hydrogen electrode. Some facultative anaerobes such as the colon bacillus reach similar low levels while others do not. Other kinds of bacteria behave still differently. *Pneumococcus* cultures, for example, show a rapid positive drift after a negative potential has been established, this is probably due to the accumulation of peroxide since it does not occur in catalase broth cultures. Representative time-potential curves are given in Fig. 18.

Fig. 18 Time potential curves illustrating the development of reducing intensities in bacterial cultures. Note the rise in potential in pneumococcus cultures in non-catalase containing media resulting from the accumulation of peroxide. The development of species-characteristic potentials is apparent. *Pneumococcus* data from Hewitt, *Cl. tetani* from Gillespie and Rettger, remainder from Burrows and Jordan.

Mechanism of Biological Oxidation.⁷ The importance of hydrogen transfer in biological oxidations was early recognized and particularly emphasized in the work of Thunberg and Wieland. Wieland postulated that in biological oxidation-reductions the hydrogen atoms of substrates were activated by specific enzymes called dehydrogenases, once activated, these hydrogen atoms were then spontaneously transferred to any suitable hydrogen acceptor. However, at about the same time, Warburg showed that oxygen may be similarly activated by an iron-porphyrin enzyme (*Atmungsferment*) and postulated that activated oxygen could spontaneously accept hydrogen from substrate molecules. The ideas of Wieland and Warburg were soon harmoniously reconciled in the now generally accepted view of biological oxidation in which substrate hydrogen is activated by dehydrogenases and molecular oxygen

⁷ In addition to the general references given in 3, see also Goddard's article "The Respiration of Cells and Tissues" in Hober: *Physical Chemistry of Cells and Tissues*. The Blakiston Company, Philadelphia, 1945, and Oppenheimer and Stern. *Biological Oxidation*. Nordemann Publishing Co., Inc., New York, 1939.

only antibodies to a somatic antigen are protective (see Chapter 33). Burrows (1953) notes a more subtle distinction of this kind with *V. cholera*; the complete O antigen is a better immunizing agent than the endotoxin against asymptomatic infection of the intestine in the guinea-pig; whereas endotoxin effectively immunizes mice against the predominantly toxic infection that follows intraperitoneal injection of the living vibrio.

It was, however, in the case of the motile bacilli, possessing flagellar and somatic antigens, that the problem of the different immunizing value of different bacterial antigens was first stated in its clearest and most explicit form by Felix and his colleagues (see Felix 1924). The results of subsequent studies strongly support his contention that the flagellar antigens, and their corresponding antibodies, play little if any part in specific antibacterial immunity, whereas the heat-stable somatic antigens and their corresponding antibodies are all-important.

Arkwright (1927) immunized guinea-pigs by the injection of vaccines prepared from different strains of *Salm. typhi* and *Salm. paratyphi A*, and subsequently tested their resistance by the injection of living virulent bacilli.

With *Salm. typhi*, a vaccine prepared by the use of a smooth, motile, virulent strain (containing the flagellar antigen and the surface antigen IX) produced a significant increase in resistance. A vaccine prepared from a rough, motile variant (containing the flagellar antigen but not the surface antigen IX) did not. With *Salm. paratyphi A* four vaccines were used: (1) a smooth, motile strain, with the flagellar antigen and the surface antigens I, II; (2) a non-motile, smooth variant, with no flagellar antigen but retaining the surface antigens I, II; (3) a rough, motile variant, with the flagellar antigen but without the surface antigens I, II; and (4) a rough, non-motile variant containing neither the flagellar antigen nor the surface antigens I, II. Vaccines (1) and (2), containing the antigens I, II, produced a marked increase in resistance. Vaccines (3) and (4), from which this antigen was absent, did not.

Ibrahim and Schutze (1928) obtained analogous results in the immunization of mice against *Salm. typhi-murium*. They found that the R variants, in which the specific polysaccharide antigen was absent, were ineffective as immunizing agents. The S variants, containing the specific polysaccharide antigen, produced a significant increase in resistance.

Experiments, in which untreated mice and mice vaccinated with different bacterial suspensions were submitted to the risk of natural infection during a long-continued experimental epidemic of mouse typhoid, also yielded entirely concordant results (Greenwood, Topley and Wilson 1931). The total numbers in each of the vaccinated groups were large—over 300 mice—so that the difference noted may be regarded as certainly significant. The results are summarized in Table 72.

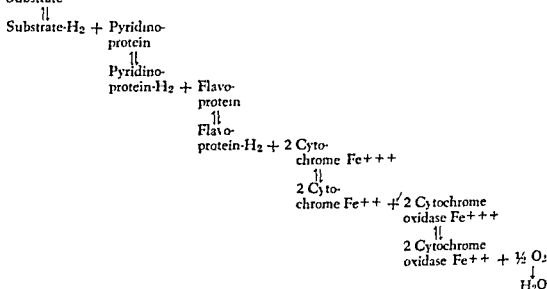

The column giving the antigenic structure shows the components on the surface of the bacterial cells and those carried by the flagella. All vaccines except E were saline suspensions, killed by heat and formalin. Vaccine E—a killed broth culture—was included because of the possibility that some bacterial product of immunizing value might be liberated into the culture fluid. The measure of resistance—the mean survival time in the epidemic cage limited to 60 days—was selected for reasons that will be referred to later. The significance of the standard error, which is attached to each survival time, has been considered in Chapter 43.

It will be seen that the control and vaccinated groups can be divided into three classes on the basis of their survival time. The unvaccinated mice lived, on the average, for 26.26 days, and were thus significantly less resistant than any other group. The groups D, B and A were slightly more resistant. This increased resistance was clearly not specific. The rough polysaccharide antigen was not concerned, for the *Staph. albus* vaccine did not contain it. The flagellar antigens of *Salm. typhi-murium* were not concerned, for neither

acts as a hydrogen acceptor only after activation by Warburg's respiratory enzyme.⁸ The dehydrogenases of Wieland have been found to consist of a specific enzyme protein and a low molecular weight coenzyme which undergoes reversible oxidation-reduction. The respiratory enzyme of Warburg functions in respiration by catalyzing the oxidation of other iron-porphyrin protein enzymes, the cytochromes, by molecular oxygen, and for this reason has been given the functional name, cytochrome oxidase. Interposed in the train of hydrogen and electron transport between the dehydrogenases and the cytochromes is another type of respiratory enzyme, the flavoprotein, which is reduced by the dehydrogenases and oxidized by the cytochromes. Thus, there is a clear and continuous pathway for hydrogen and electron transport from the substrate to molecular oxygen, which is illustrated in the accompanying diagram.

AEROBIC OXIDATION OF SUBSTRATES

Substrate

Net Reaction

In most aerobic organisms this system is complete and functional, but in facultative and obligate anaerobes, portions of the hydrogen transport chain may be absent or non-functional (*vide infra*). In anaerobic respiration, the hydrogen and electrons of substrates are not transferred to molecular oxygen but to other substrates instead. The iron-porphyrin catalysts are not involved in anaerobic respiration, but the flavoproteins may sometimes act as intermediate carriers.

Respiratory Enzymes in Bacteria.⁹ Although bacteria contain very active respiratory enzymes, much less is known about their chemical nature than about similar enzymes in yeast and in the tissues of higher animals,

⁸ Kluyver and Donker: *Chem. Zelle Gewebe*, 1926, 13:134.

⁹ See Porter: *Bacterial Chemistry and Physiology*. John Wiley and Sons, Inc., New York. 1946. Chapter 6.

but Koprowski and Cox (1951) report on its successful use in 29 patients bitten by dogs that were proved to be rabid. Possibly combined active and passive immunization may prove better than either separately. Experiments made on this point with hamsters were not convincing (Koprowski *et al.* 1950), but later observations on guinea-pigs and dogs yielded more hopeful results (Koprowski and Black 1951). How antiserum acts is doubtful. Presumably it neutralizes the extracellular virus around the bite; if so, it must be given within 2-3 days of the time of infliction of the wound before the virus has gained access to the neurons and passed beyond the reach of the antibody. It should be followed by a 7-day course of vaccine treatment. For much useful information on rabies, see the monograph by Remlinger and Bailly (1938*a*), the article by Johnson (1952), the review by Rhodes (1916) on anti-rabic treatment, and the series of papers on laboratory diagnosis, vaccine production and testing, and the preparation of hyperimmune serum edited in book form by the World Health Organization (Report 1951).

PSEUDORABIES

SYNONYMS: Mad itch: Infectious bulbar paralysis: Aujeszky's disease.

This disease, which was described by Aujeszky in 1902, has only recently attracted much attention. It appears to be an acute infection of the central nervous system affecting dogs, cats, cattle, horses, pigs, goats, sheep, rats, and mice, but not man. Though originally met with in Hungary, it has now been reported from a number of other European countries and from both North and South America. Unlike rabies the incubation period is very short—only a matter of hours—the onset is brusque, there is intense pruritus, which often completely dominates the clinical picture, the mental faculties are preserved, paralysis occurs very late and does not affect the lower jaw, the disease lasts only 21-48 hours, and sudden death is common (Remlinger and Bailly 1931). Except in pigs, the case-fatality rate is usually very high. The mode of infection is still in doubt. According to Shope (1935), the disease in cattle is very fatal but non-contagious, whereas in pigs it is relatively mild but highly contagious. Shope believes that in pigs infection occurs by the nose, and that the abraded skin of cattle can probably be infected from contact with the pig's snout. A study of neutralizing bodies in the serum suggests that pseudorabies is a highly prevalent but unrecognized disease in the hogs of the Middle West. There is some evidence that the disease is spread by rats, and that pigs may become infected by feeding on contaminated material.

The disease can be reproduced experimentally in most animals, though monkeys appear to be fairly resistant. In the rabbit, which is the most susceptible of the small laboratory animals, the disease exhibits a diverse and striking symptomatology. Infection is possible by practically any route. Intracerebral inoculation gives rise in 20-40 hours to a condition of wild excitement, accompanied by salivation, grinding of the teeth, blindness, and later coma and death. In rabbits injected subcutaneously the incubation period is 50-75 hours; the animals then start scratching and biting the site of inoculation; their efforts become increasingly savage till the skin is hairless, abraded, and bleeding; feebleness sets in, and death occurs in a state of collapse 6-24 hours after the onset of pruritus (Shope 1931). The clinical picture, however, is very variable, and may assume an encephalitic, pseudo-herpetic, meningeal, paralytic, pruriginous, fulminating, or even abortive form (Remlinger and Bailly 1934). Some animals can be infected by feeding.

chiefly because it has been very difficult to obtain active enzyme extracts from bacterial cells.

Dehydrogenases Dehydrogenases consist of a specific protein, or apoenzyme, combined with a reversibly oxidized and reduced coenzyme. They oxidize metabolites and are in turn reoxidized by other enzymes, not by molecular oxygen. Dehydrogenases possess a high degree of specificity for the substrate which they oxidize, and are usually named on the basis of their substrate specificity, *i.e.*, lactic dehydrogenase, succinic dehydrogenase, etc. This substrate specificity is a function of the protein component, since a single coenzyme may be a part of several different dehydrogenases

The specific protein combines reversibly with both coenzyme and substrate. The actual oxidation-reduction probably occurs while all three are in physical combination.

Two general types of dehydrogenases are found in bacteria and in other containing either di- or enzymes. The provisional is illustrated

diphosphopyridine nucleotide

The structure of TPN (coenzyme II) is identical with that of DPN except for the presence of an additional molecule of phosphoric acid which is probably esterified to one of the hydroxyl groups of the pentose residue. Only the pyridine ring of both DPN and TPN undergoes reversible oxidation-reduction as indicated in the accompanying equation.

so-called "trotting" variety, the itching is less severe, but the animal periodically drops every now and again, as if dead, and then rises in a few minutes and resumes its trot. Pathologically, no characteristic lesions have been found, but there is a mild degree of meningo-encephalitis. Early attempts to transmit the disease failed, possibly because the animals were not observed long enough. Later, Cuillé and Chelle (1936, 1938) in France were successful in reproducing the disease in susceptible sheep by subcutaneous, intra-ocular, epidural, and intracerebral inoculation of suspensions of brain and spinal cord. About the same time workers in Scotland (see Gordon 1946, Greig 1950) reported the occurrence of the disease in sheep that had been injected about 2 years previously with a vaccine against louping-ill. This had been made up with a suspension of brain, cord, and spleen from sheep inoculated intracerebrally with louping-ill virus, and had been preserved with 0.35 per cent. formalin. The incubation period of the natural disease appears to be 2 years or longer. After subcutaneous injection of infective material it is usually 15 months or more, and after intracerebral injection 5-7 months. Only a proportion of injected sheep, however, develop the clinical disease. Wilson, Anderson and Smith (1950) showed that the virus would pass through a gradocol membrane of 41 $m\mu$ A.P.D. Finer filters were not tried. The virus must therefore be less than 16 $m\mu$ in diameter. It is very resistant. It survives drying for at least 2 years if kept in the ice-chest, and is not killed by 0.35 per cent. formalin. There is some reason to believe that the virus may remain latent in rams, which can transmit infection to their offspring. The ewe may remain unaffected, and bear healthy lambs by another ram (see Andrewes 1950).

We append brief descriptions of two animal diseases whose position in our rough scheme of classification is very doubtful.

SALIVARY GLAND VIRUS OF GUINEA-PIGS

Cole and Kuttner (1926) observed greatly swollen epithelial cells in the salivary glands of guinea-pigs; they were found in 84 per cent. of full-grown animals. Injection of a suspension of the affected submaxillary glands intracerebrally into young guinea-pigs was followed by fever, cerebral irritation, and death in 5 to 7 days, with diffuse subacute meningitis. In the exudate large numbers of cells were found similar to those in the salivary glands. Similar cells were also seen in the lesions resulting from inoculation of the same suspension into the testicle, lung, tongue, and submaxillary glands of young guinea-pigs. Markham (1933) recorded the occasional finding of characteristic inclusions in the epithelium of the convoluted tubules in the kidney of naturally infected animals. The virus is destroyed at 54° C. in 1 hour; it survives for 11 but not for 28 days in 50 per cent glycerol. It passes through a Berkefeld N candle. The virus appears to give rise to no clinical symptoms in naturally infected guinea-pigs. Infected guinea-pigs are immune to the intracerebral inoculation of virus; in the serum of these animals neutralizing bodies can be demonstrated (Andrewes 1930). More recently Kuttner and Wang (1934) described the presence of acidophilic intranuclear inclusion bodies in the submaxillary glands of hamsters, white mice, and wild rats; each of these animals appears to be infected by a specific virus. Similar inclusion bodies have also been noted in the salivary glands of new-born infants. They are not

The pyridinoproteins are soluble, relatively easily extracted from cells, and their reduced forms are reoxidized by flavoproteins. In bacteria, the malic, lactic and 3-phosphoglyceraldehyde dehydrogenases are DPN-proteins, while glutamic acid dehydrogenase is a TPN-protein. The *cytochrome-linked dehydrogenases* are associated with the insoluble submicroscopic cell particles. In crude preparations they react with oxygen through the cytochrome system, but there is evidence that an additional hydrogen carrier is involved. It may be a flavoprotein or perhaps cytochrome *b*. The succinic and formic dehydrogenases of *Bact. coli* and the lactic dehydrogenase of the gonococcus are cytochrome-linked.

The oxidation of substrates by dehydrogenases may be conveniently studied in the absence of other respiratory enzymes by means of a technique introduced by Thunberg. In this procedure, the dehydrogenase is reduced by its specific substrate and reoxidized by a reversibly oxidized and reduced dye possessing a suitable oxidation-reduction potential.

When the oxidized form of the dye is colored and the reduced form is colorless (methylene blue, for example), the rate of such a reaction may be measured in terms of the rate of decolorization of the dye in the absence of oxygen.

Flavoproteins. The flavoproteins are respiratory enzymes containing either riboflavin phosphate or flavin adenine dinucleotide as coenzymes.

*flavin adenine dinucleotide*

In both riboflavin coenzymes, oxidation-reduction is confined to the isoalloxazine nucleus.

*oxidized form**reduced form*

Derivatives of riboflavin are apparently present in all bacteria and are found in especially large amounts in some anaerobes. Flavoprotein enzymes fall into two functional groups. The *oxidases* catalyze irreversible oxidations of substrates and react directly with oxygen to form hydrogen peroxide.

These flavoprotein oxidases have been studied almost entirely in animal tissues, and no clear-cut demonstration of such an enzyme in bacteria has been made. *Lactobacillus delbrueckii* contains an auto-oxidizable flavoprotein which is probably responsible for the oxygen uptake of this cytochrome-free organism, but the flavoprotein has not been shown to react directly with metabolites. Most peroxide formation in bacteria is probably due to flavoprotein-catalyzed reactions.

Other flavoproteins function in hydrogen transport as the link between the dehydrogenases and the cytochromes.

These flavoproteins catalyze reversible reactions and do not react with either metabolites or molecular oxygen. Flavoproteins of this type have been studied in *Bact. coli*, and they probably are found in all cytochrome-containing bacteria.

Iron-Porphyrin Protein Enzymes. Several important respiratory enzymes have iron-porphyrin compounds as coenzymes. These iron-porphyrins are closely related to, but not identical with, the heme of hemoglobin. Only the iron atom of the iron-porphyrin undergoes reversible oxidation-reduction. Almost all aerobic cells contain three iron-porphyrin protein pigments, the cytochromes *a*, *b* and *c*. Each of the cytochromes may readily be identified spectroscopically by four sharp absorption bands in the visible spectrum when in the reduced ferrous state, and their presence or absence in a relatively large number of bacteria has been determined.

The cytochromes are almost invariably present in aerobic bacteria and absent in obligate anaerobes, while facultative anaerobes may be lacking one, two or all of the cytochromes. Although some cytochrome-free bacteria, such as *L. delbrueckii*, rapidly consume oxygen, there is no doubt that the cytochromes are intimately associated with sustained aerobic growth and metabolism.

Cytochrome oxidase, Warburg's respiratory enzyme, is a portion of the sub-microscopic particulate structure of the cell, but it may be brought into solution or stable suspension by treatment with ultrasonic vibrations. Although cytochrome oxidase has never been isolated in pure form, its absorption spectrum and its behavior with inhibitors show that it is an iron-porphyrin protein.

The cytochrome system functions in respiration as the last link between substrate and oxygen. The path of the electron and hydrogen transport over the cytochrome system may be divided into three steps:

1. Reduction of cytochrome

2. Reduction of cytochrome oxidase

3. Reduction of oxygen

No peroxide can be detected in oxidations catalyzed by the cytochrome system. The mechanism of the reaction between cytochrome oxidase and oxygen (activation of oxygen) is unknown, but Warburg has suggested that oxygen forms a loose combination with cytochrome oxidase similar to oxyhemoglobin; in this complex, the oxygen is activated and accepts electrons and hydrogen to form water. The oxygen consumption of almost all cells is more or less completely inhibited by hydrogen cyanide and carbon monoxide, and the carbon monoxide inhibition is removed by irradiation with visible light. Only the iron-porphyrins combine with both hydrogen cyanide and carbon monoxide, the carbon monoxide compounds being light-dissociable. The importance of the cytochrome system in aerobic respiration is shown by the almost complete inhibition of oxygen uptake by cyanide or carbon monoxide in cytochrome-

containing cells. It has been found that in respiring yeast cultures each molecule of cytochrome is oxidized and reduced 4000 times a minute, a rate sufficient to account for all the oxygen uptake of the cultures. The portion of bacterial respiration not inhibited by cyanide or carbon monoxide is probably carried out by auto-oxidizable flavoproteins or by other respiratory enzymes with reversibly oxidized and reduced substances such as phthiocol, a yellow pigment of the tubercle bacillus, or pyocyanine, a pigment produced by *Ps. pyocyanea*, as coenzymes.

Most organisms contain an enzyme called *catalase* which decomposes hydrogen peroxide.

The catalase crystallized from beef liver by Keilin and Hartree is an iron-porphyrin protein and it is generally accepted that catalase from other sources has a similar chemical nature. Catalase is present in almost all aerobic bacteria and some facultative anaerobes, but under usual conditions of culture it cannot be detected in *Clostridium* and some of the streptococci, lactic acid bacteria and dysentery bacteria.

The *peroxidases* are enzymes, probably iron-porphyrin proteins, which catalyze the oxidation of substrates by hydrogen peroxide. Their distribution in bacteria parallels that of the cytochromes and catalase, and their function in bacterial metabolism is unknown.

*Hydrogenase*¹⁰ is a bacterial enzyme which catalyzes the reaction of the normal hydrogen electrode

In the presence of hydrogenase and molecular hydrogen, many substrates are reduced.

Hydrogenase activity was first found in the autotrophic hydrogen bacteria and much later in many heterotrophic facultative anaerobes such as *Bact. coli*. Recently, hydrogenase has been observed in the strongly aerobic *Azotobacter* where it is apparently involved in some manner with nitrogen fixation. Although hydrogenase has never been isolated, it is probably an iron-porphyrin protein because it is inhibited by hydrogen cyanide and by carbon monoxide, the latter inhibition being light-reversible, and because it is not found in cultures grown on iron-deficient mediums. Hydrogenase is inactivated by molecular oxygen, and it has been suggested that the Fe^{++} form is active while the Fe^{+++} form is inactive.

The Relation of Bacteria to Molecular Oxygen. The bacteria differ from one another in their relationship to molecular oxygen. Certain bacteria, the *obligate aerobes*, require ready access to air, growing feebly or not at all

¹⁰ Recent investigations on hydrogenase are discussed in considerable detail by Lipmann: *Ann. Rev. Biochem.*, 1943, 12:5, and Stephenson: *Antonie van Leeuwenhoek*, 1947, 12:33.

in its absence. Such organisms may possibly lack certain respiratory enzymes necessary for anaerobic respiration, but there is no proof of this. It is also possible that end products of their anaerobic metabolism are toxic to them, or that they cannot grow in the presence of strong reducing intensities. This group includes such well known bacteria as the nitrifying bacteria, some of the sulfur bacteria, *Bacillus subtilis* and related forms, *Azotobacter*, the diphtheria bacillus, the cholera vibrio, and others.

However, most bacteria can grow in the complete or virtual absence of molecular oxygen. Two types of anaerobic bacteria may be distinguished. The most numerous are the *facultative anaerobes*, which respire with equal facility in the presence or absence of molecular oxygen. In broth cultures, the dissolved oxygen is soon exhausted and, after a preliminary period of aerobic growth, the culture continues to develop under essentially anaerobic conditions. The *obligate anaerobes* are unable to grow in the presence of molecular oxygen, and oxygen is actively toxic to them; vegetative cells die very quickly upon exposure to air, although spores are highly resistant. Members of the genus *Clostridium*, together with microaerophilic forms which tolerate very low concentrations of oxygen, are usually included in this group.

Bacteria are unexcelled in the possession of powerful and varied means for obtaining energy from nutrients in the absence of oxygen. The energy obtained from a given quantity of nutrients is usually much less under anaerobic conditions than in the presence of oxygen, because oxidation of substrates is less complete, and anaerobic metabolism is characterized by a rapid utilization of oxidizable substrates and a great accumulation of partially oxidized end products.

Bacteria carry out energy-yielding oxidations under anaerobic conditions in a number of ways. Inorganic compounds may be reduced and thus replace molecular oxygen as the final electron acceptor. For example, ammonia and a single organic compound such as lactic acid are sufficient to support the aerobic growth of *Bact. coli* in a medium of inorganic salts, but growth in the absence of air does not occur unless nitrate ion is also present and the nitrate reduced to nitrite by the enzyme nitratase. Organic compounds may also act as final oxidants in anaerobic respiration. Thus the reduction of fumaric acid to succinic acid by succinic dehydrogenase may replace the reduction of nitrate in supporting the anaerobic growth of *Bact. coli*. Another energy-yielding reaction is a reaction between two substrates in which one is reduced and one is oxidized. This type of reaction is called a *dismutation*, and is a very common type of anaerobic reaction in bacteria. For instance, acetaldehyde may dismutate to acetic acid and ethanol.

While carbohydrate is the chief energy source for both aerobic and anaerobic heterotrophes, certain of the obligate anaerobes possess only a very limited ability to metabolize carbohydrate, and an important source of energy for these bacteria appears to be the coupled oxidation-reduction of pairs of amino acids. *Cl. sporogenes*, for example, carries out the reaction between alanine and proline at a rapid rate¹¹ (see accompanying equation).

CHAPTER 88

FILTRABLE VIRUS DISEASES—*Continued*

D. GROUP CHARACTERIZED BY CATARRHAL OR GENERALIZED INFECTION

MEASLES

MEASLES is a highly infectious disease of human beings, which is endemic throughout the world. In Europe and America epidemics tend to occur in alternate years, as a fresh susceptible population of children grows up. Among civilized peoples it is chiefly a disease of childhood, fairly mild in itself, but when complicated by respiratory infections—as it so often is—is apt to be attended by a high case-fatality rate. Introduced, however, into non-endemic areas it affects young and old alike, and takes on a more malignant character. When it was imported, for example, into the Fiji islands in 1875, it carried off 20-25 per cent. of the entire population (see Brueker 1938). Most children exposed to infection for the first time contract the disease. For instance, in the epidemic in southern Greenland described by Christensen and his colleagues (1953) the attack rate was 999 per 1,000. There is some evidence, however, that during epidemics a small proportion of children may develop a latent infection resulting in a temporary or sometimes permanent immunity (see Halliday 1928, Stocks and Karn 1928, Enders 1941).

In this country measles is a disease of winter and spring, the maximum mortality usually being recorded in April. The number of deaths is now far less than it used to be—partly perhaps because of the better nutritional state of the children and partly because of the introduction of prophylactic serum and of the antibiotic treatment of secondary infections. The incubation period is usually 10-11 days, depending on whether the fever or the rash is counted as the beginning of the disease. Infectiousness appears to be greatest during the catarrhal stage, but lasts from about 4 days before to 5 days after the appearance of the rash. Comparing measles, varicella, and mumps, Simpson (1952) found that the age distribution of these diseases was inversely related to their degree of infectiousness, measles attacking the younger and mumps the older children with varicella coming in between.

Anderson and Goldberger (1911) first recorded evidence indicating that measles could be experimentally transmitted to monkeys. The experiments of Nicolle and Conseil (1911, 1920) likewise suggested that monkeys were susceptible. The most convincing evidence, however, was brought by Blake and Trask (1921). These workers were able, by the intratracheal inoculation of filtered and unfiltered nasopharyngeal washings taken from measles patients 6 days before to 22 hours after the appearance of the rash, to produce in monkeys (*Macacus rhesus*) a disease closely simulating human measles. After an incubation period of 6 to 10 days, there developed a characteristic group of symptoms

As already mentioned, the obligate anaerobes contain none or very little of the iron-porphyrin respiratory enzymes, a definite indication of enzymatic deficiency. However, the toxicity of molecular oxygen to these bacteria requires more explanation than their lack of oxygen-transporting enzymes. The catalase theory is based on the discovery that certain bacteria produce hydrogen peroxide in amounts sufficient to be toxic to themselves.¹² In cultures of those species which do not produce catalase and are peroxide-sensitive, peroxide accumulates and the culture becomes self-sterilizing; the pneumococcus is an example of this type of microorganisms. Those bacteria which produce catalase decompose the peroxide as it forms and it does not accumulate to toxic concentrations. The obligate anaerobes are peroxide-sensitive and do not form catalase. Hence it has been suggested that these organisms form peroxide rapidly in the presence of air and therefore oxygen is toxic to them. Although this theory is accepted by some, it entirely lacks supporting evidence, for all attempts to demonstrate peroxide in cultures exposed to air have failed.

It has also been proposed that the reducing intensity of the medium is the factor governing whether or not growth will occur. Experimental evidence, both direct and indirect, has been presented which indicates that a certain degree of reducing intensity is essential to the germination of tetanus spores¹³, the positive limit appears to be about +50 millivolts at pH 7.0. It has been suggested that this accounts for the failure of tetanus spores to germinate in healthy tissues in the absence of trauma or secondary infection as is sometimes observed. Since a sufficient reducing intensity cannot be maintained in the presence of oxygen, oxygen is toxic. It is not clear why such a reducing intensity should be required. Possibly some of the respiratory enzymes of the obligate anaerobes are oxygen-labile, i.e., active in the reduced state and inactive in the oxidized state, as are some of the bacterial hemolysins (p. 207) or hydrogenase (p. 73), or perhaps the substrates of some of the enzymes of these organisms are unstable under aerobic conditions.

The Role of Phosphorylated Compounds in the Conservation and Utilization of the Energy Liberated in Respiration.¹⁴ Phosphorylated organic compounds are of primary importance in the energy metabolism of bacteria and all other living things. Phosphorylated compounds of biological importance may be conveniently divided into two groups according to the energy liberated upon hydrolysis of the linkage involving the phosphorus.

healthy home contacts from attending school, provided that they are kept under observation. In view of the high complication rate due to cross-infection with hæmolytic streptococci, treatment at home rather than in hospital is advocated for patients with uncomplicated measles (see Wright 1915).

The specific prophylaxis of measles is greatly aided by the use of human serum or its derivatives. The new-born infant, so long as its mother has had measles, is passively protected for the first 4-6 months of life. From then up till 12 months of age it is advisable to prevent an attack completely. After that the aim of serum prophylaxis should be to produce an attenuated attack. However, in weakly debilitated children, in children suffering from another disease, and sometimes in hospitals and institutions, complete protection should be aimed at. When complete protection is attained, the duration of the resulting immunity is 3-4 weeks, and the patient is subsequently susceptible to infection. The immunity following an attenuated attack appears to be permanent.

The various products that may be used are : (a) *Whole blood*. This is of value mainly in general practice when blood may be withdrawn from the mother or other member of the household and injected directly into the child. The objection to whole blood is that it may sensitize the recipient to rhesus agglutinin : it should therefore be avoided, if possible, in female children (Marshall 1918). (b) *Adult serum*. This is satisfactory if the blood is withdrawn from normal adults who have previously suffered from measles, but the requisite dosage is fairly high (see Brincker 1936). (c) *Convalescent serum*. Serum prepared from the blood of convalescent patients taken 7-10 days after defervescence has about twice the protective power of normal adult serum and hence can be given in half the dosage. (d) *Placental extract*. This was recommended by McKhann and Chu (1933) and McKhann (1937). In potency it occupies a place midway between adult and convalescent serum. The difficulty, however, of extracting the placental globulins and the high proportion of local and systemic reactions that follow its use have precluded it from general acceptance. (e) *Gamma globulin*. This can be extracted from human plasma either by the ethanol-water method of protein fractionation devised by Cohn and his colleagues (1946) or by the ether method of Kekwick and Mackay (1951). Both products contain the specific antibody in greater concentration than convalescent serum, cause only few and mild reactions, and prove on the whole very satisfactory in practice (Cohn *et al* 1944, Stokes *et al* 1944, Ordman *et al* 1944, Greenberg *et al* 1944, Report 1950).

Which of these preparations should be selected must depend on circumstances. In the past adult serum has been extensively used, with a considerable measure of success. The occasional occurrence, however, of serum hepatitis after its use, sometimes with serious and even fatal effects (see p 2207), has brought it into gradually increasing disfavour. Attempts to destroy the hepatitis virus in the serum by ultraviolet irradiation have proved disappointing, and the tendency now is to replace serum as completely as possible by gamma globulin, which, so far as present experience goes, appears to be free from the risk of causing this particular complication.

When gamma globulin is not available and adult serum has to be used, it should be injected intramuscularly, preferably into the vastus externus. Complete protection is difficult to secure, unless large doses are given within 5 days of exposure to infection. For attenuation, the dose may be estimated, in millilitres, as the age of the child multiplied by 2 when the injection is made within 5 days of exposure,

of rubella proved refractory to experimental infection, suggesting that they had previously suffered from the disease in a latent or sub-clinical form. Krugman and his colleagues (1953) were likewise successful in transmitting the disease experimentally to human volunteers by intramuscular injection of blood serum and by nasal and oral administration of nasopharyngeal washings. In their experience the incubation period was only 9-16 days. The virus can be preserved at -70°C . for at least 9 months. Anderson (1954) reported its cultivation in roller tube tissue cultures of adult monkey kidney. (See also Habel 1942.)

Gregg (1941) and Swan and his colleagues (1943, 1944) in Australia drew attention to the prevalence of abnormalities in infants born of mothers who had suffered from rubella during pregnancy. Congenital cataract, deaf-mutism and cardiac disease are the commonest defects, but numerous others such as strabismus, cleft palate, spina bifida, and microcephaly have been reported. There is reason also to believe that pregnancy may end in stillbirth (Swan 1948). Complications are most likely if rubella occurs in the first 3 or 4 months of pregnancy, the 2nd and 3rd being apparently the most dangerous (Swan and Tostevin 1946). These observations have been confirmed in many other countries (see Ober *et al* 1947, Clayton-Jones 1947). How frequently maternal rubella in pregnancy results in abnormalities of the infant, it is difficult to say; the few figures available are rather conflicting. Rubella is probably not the only virus disease to be transmitted to the foetus. Aycock and Ingalls (1946) bring evidence to suggest that poliomyelitis during pregnancy may lead to congenital abnormalities; and there is other evidence that measles and chicken-pox may occasionally act in the same way.

In view of these findings it is highly desirable, for girls at any rate, to have rubella before puberty. Whether it is justifiable to expose them deliberately to infection or to transmit the disease to them experimentally, is open to discussion, but so long as the subjects are healthy and there is no fear of any other infection being transmitted simultaneously there is a good deal to be said for it. It should be remembered that the disease produced experimentally is contagious and that it may not be accompanied by a rash. Care should therefore be taken to prevent the infection spreading to pregnant women who have not had the disease. Pregnant women without a history of rubella who are exposed to infection should be given gamma globulin, preferably made from convalescent serum, as soon as possible in the hope that it may forestall the disease, but so far the evidence of its value in this respect is unconvincing (see Korns 1952, Anderson and McLorinan 1953).

MUMPS

Mumps is an infectious disease of human beings characterized by a non-suppurative enlargement of the parotid glands, and sometimes of the testicles. It is commonest between 5 and 15 years of age, but often attacks young adult recruits to the fighting services. Most cases occur in the spring. The incubation period is variable; it is usually given as 12-26 days with 18 days as the commonest. Infectivity probably lasts from a day or two before symptoms appear to the disappearance of the glandular swelling. Transmission occurs directly or indirectly from infected saliva. The infectiousness is much lower than that of measles or chicken-pox, and latent and sub-clinical attacks are frequent (Maris *et al* 1946, Simpson 1952). The disease seldom proves fatal, and even the meningitis and encephalitis that may follow it are usually benign. Second attacks are uncommon.

The Role of Phosphorylated Compounds

two compounds. The differences in chemical behavior between compounds with low energy and high energy phosphate bonds are similar to those between ethyl acetate, an ester of acetic acid and ethanol, comparable to low energy phosphorus compounds, and acetyl chloride, an anhydride of acetic acid and hydrochloric acid, comparable to high energy phosphorus compounds. When water is added to ethyl acetate, no heat (energy) is evolved and the ester is not hydrolyzed. If water is added to acetyl chloride, heat is evolved with explosive violence and acetyl chloride is quickly split into its two components. Because of the differences in energy content, compounds with low energy phosphate bonds can never be in reversible equilibrium with compounds containing high energy bonds. Compounds with phosphate bonds of the same energy content may be in equilibrium with each other, and high energy phosphate bonds may be used to form low energy phosphate bonds.

In both the autotrophic and heterotrophic bacteria, the energy released in the oxidation-reduction reactions of respiration may be used to convert inorganic phosphate or the organic phosphate of low bond energy compounds into high phosphate bond energy compounds

Specific examples of this general process are discussed in other portions of the chapter (*vide infra*).

The adenine nucleotides are of particular importance in the transfer of high energy phosphate bonds from place of generation to place of utilization. The high energy phosphate bonds generated in respiration are transferred to adenosine monophosphate (AMP, adenylic acid) or, as is more often the case, to adenosine diphosphate (ADP) and conserved in the form of ATP.

The energy-rich phosphate bonds of ATP are used by bacteria in the assimilation of carbon dioxide, the phosphorylation of carbohydrates and the synthesis of compound sugars (*vide infra*). More generally, it has been demonstrated that ATP is involved in muscular contraction, the synthesis of peptide bonds, the oxidation of fatty acids and many other biochemical processes.

in the infected chick embryo. One, the V antigen, is closely linked with the virus in the amniotic and allantoic fluids: the other, the soluble or S antigen, is smaller in size and is present chiefly in the membranes (Henle, Harris and Henle 1948). In mumps, antibodies to the S antigen appear early in the disease and reach high levels before antibodies to the V antigen begin to rise. During early convalescence both antibodies are demonstrable in high titre. Later, the S antibodies usually decline more quickly than the V, so that after some years only V antibodies may be found. S antibodies may be detectable on the 1st or 2nd day of the disease, and are sometimes of value in the diagnosis of meningo-encephalitis in the absence of glandular swelling. (c) *Hæmagglutination-inhibition test* The patient's serum is examined for its ability to prevent agglutination of chicken red corpuscles by the virus. The usual two specimens of sera, taken during the acute stage of the disease and during convalescence respectively, are required to show a rise in antibody titre. The test is said to be inferior in value for diagnostic purposes to the complement-fixation test (Lundback 1949). (d) *Modified human red cell agglutination test*. Burnet (1946) found that human red blood corpuscles treated under certain conditions with mumps virus were specifically agglutinated by mumps antibody. This test is very sensitive and the end-point may be difficult to determine (Aikawa and Meiklejohn 1949). (e) *Serum neutralization test*. Gotlieb and his colleagues (1953) developed a neutralization test for mumps in the chick embryo using serial dilutions of inactivated serum and constant amounts of virus. Convalescent sera showed a wide range of neutralizing activity from 1/8 to over 1/2,000. The neutralizing titres did not run parallel to those obtained by the complement-fixation and hæmagglutination-inhibition tests, which themselves yielded different results. (f) *Skin test*. When a suspension of heated inactivated mumps virus from the parotid glands of infected rhesus monkeys is injected intradermally into a person who has had mumps, an erythematous reaction occurs reaching 10–15 mm. or more in diameter within 48 hours (Enders *et al.* 1946). As an index of immunity the test appears to be of much the same value as the complement-fixation test (Henle *et al.* 1951). (For serological confusion with the Newcastle virus, see p. 2230.)

Protection.—Attempts to produce active immunity against mumps are still in the experimental stage. Virus grown in eggs may be inactivated by ether, formalin, or ultraviolet irradiation, or a living attenuated virus may be used. None of these vaccines, however, has so far proved capable of giving rise to a firm persistent immunity (see Stokes *et al.* 1946, Habel 1951, Bashe *et al.* 1953). It should be added that mumps is not usually a serious disease, and vaccination should seldom be called for except in special circumstances, such perhaps as the protection of hospital staffs and of groups of young adults undergoing military training. Babies born of mothers that have had mumps are immune by virtue of passively transferred antibody. Some degree of passive protection may perhaps be conferred by the injection of convalescent serum, or better gamma globulin, within five days of exposure to infection. The gamma globulin should be prepared from convalescent serum and should be given in a dose of about 20 ml. to an adult. Its chief virtue is to lower the risk of developing orchitis, which so often complicates the disease in adult life (see Gellis *et al.* 1945b).

THE AUTOTROPHIC BACTERIA

Of the many types of physiological activity occurring among the bacteria, that of the so-called *autotrophes* is unique in biochemical physiology. The respiratory mechanisms of chemosynthetic organisms are concerned, for the most part, with the oxidation of organic molecules. Such organisms are generally spoken of as *heterotrophes*, organisms which are dependent upon the organic substances synthesized by other living cells. The autotrophic bacteria, however, derive the energy necessary to their life processes from the oxidation of inorganic compounds of nitrogen, sulfur and iron, and obtain nitrogen from ammonium salts and carbon from carbonate or carbon dioxide.

The Nitrifying Bacteria. Of the autotrophic bacteria perhaps the most important single group is that of the microorganisms, discovered by Winogradsky in 1890, which oxidize ammonia to nitrite and nitrite to nitrate. The species of bacteria concerned are *Nitrosomonas* and *Nitrosococcus* (so-called because their cultures give the nitroso reaction in the qualitative test for nitrite) which bring about the reaction:

and *Nitrobacter* which brings about the reaction:

These equations represent the reactions from which these organisms obtain energy for maintenance and growth. In the presence of ammonia and nitrate organic compounds are not oxidized, and their presence may even inhibit growth.¹⁶ However, Boltjes has observed a favorable influence of certain protein derivatives and fatty acids upon the growth of nitrifying bacteria, and Bomeke has shown that, in the absence of ammonia and nitrite, these organisms carry out an oxidation of organic substances, presumably of endogenous origin.

The relative simplicity of the respiratory mechanisms of these two species of nitrifying bacteria has made possible a reliable determination of the free energy efficiency of these organisms. The ratio of nitrogen oxidized to carbon fixed as protoplasm has been found to be 35 for *Nitrosomonas* and 135 for *Nitrobacter*. Assuming the energy consumed in the synthesis of protoplasm to approximate that of the reduction of carbon dioxide to hexose, the efficiency of *Nitrobacter* becomes 7.8 per cent and that of *Nitrosomonas* 5.9 per cent.¹⁷ Presumably, then, about 95 per cent of the energy liberated should appear as heat, and experiment has shown this to be true. As machines, therefore, the nitrifying bacteria are not highly efficient.

The actual process of oxidation is entirely unknown; it has been suggested that hydroxylamine and hyponitrous acid may be intermediates, but there is no evidence for this.

¹⁶ For example, 0.015 M glucose completely inhibits *Nitrobacter* in liquid media and somewhat higher concentrations, 0.2 per cent, are necessary to inhibit growth in sand media or soil. (Coleman: *Centralbl. f. Bakt.*, 1908, Abt. II, 20:401, 485.)

¹⁷ Calculated on a free energy rather than heat of combustion basis. Cf. Bass Becking and Parks: *Energy Relations in the Metabolism of Autotrophic Bacteria*. *Physiol. Rev.* 1927, 7:85.

Robertson and Felix (1930) found that an antiserum to *Cl. septicum*, containing antibodies against the heat-stable somatic antigen, but none against the heat-labile flagellar antigens, had a high protective value in mice. Henderson (1932) recorded analogous results with *Cl. chauvæi*. These results accord in general with those found in the salmonellæ. But later Henderson (1937) observed that antisera to unheated formalized *Cl. septicum* contained a protective antibody specific for a heat-labile antigen in the bacilli. The antigen had none of the qualities of the heat-labile Vi antigens, and appeared to be flagellar in nature, the protective effect being roughly proportional to the flagellar agglutination titre. Henderson suggested that flagellar antibody might exert an immobilizing effect on a motile, pathogenic bacterium and thus prevent its dissemination through the tissues.

The Efficacy of Antibacterial Immunity.

As we have already emphasized in Chapter 42, immunity may be of very varying grade. The first effect of the mechanisms that we have discussed in the present chapter is to free the circulating blood from bacteria, and so save the host from a fatal bacteræmia. The effect on the local foci of infection is less pronounced, and much less rapid. Bacteria may remain latent in such foci over considerable periods.

Thus (Topley 1929) of 64 vaccinated mice that had survived in apparent health for 28 days after an intraperitoneal injection of 1,000 virulent *Salm. typhi-murium*, 31 were found to be harbouring that organism in the spleen. We need not doubt that a complete sterilization of the tissues often occurs; but we must not identify the absence of overt illness with a complete absence of infection, or assume that illness followed by recovery is identical with a return to the uninfected state.

There is another factor which may limit the efficacy of immunity of this type. There are regions of the body in which bacterial infections are particularly dangerous, and when foci are established at these sites an immunity that is effective against lesions elsewhere seems to be of little avail. Thus Bull (1915*b*) noted that immunized animals, after rapidly freeing their blood stream of pneumococci and remaining in apparent health for several days, might later succumb to a pneumococcal meningitis. The particular susceptibility of certain regions of the body, even in the immune animal, may be an inherent feature of the animal. It may also be a reflection of variations in the distribution and efficacy of antibody in the various tissues. We shall examine this latter possibility in the next section.

In general, antibacterial immunity is, as we should expect, more variable and often less effective than antitoxic immunity

The Conditions under which Antibodies exert their Protective Action.

The union of antibody with the surface antigens of an invading bacterium clearly renders the parasite more susceptible to the defence mechanisms of the infected host—for example, to the lethal and bacteriolytic action of complement and to phagocytosis. The importance for protection of the host of phenomena like precipitation and agglutination is less well established. The formation of visible precipitates, or of an agglutinated mass of bacteria, in the tissues or tissue fluids of an immune animal cannot take place unless there is an adequate concentration of antigen, either in the form of soluble products of bacteria, or of bacteria themselves.

In discussing the functional significance of precipitins Cannon (1940) suggests that specific aggregates in the body range in size from molecular aggregates up to large precipitates. The *in vivo* formation of large precipitates is, however, mostly a matter of

The Sulfur Bacteria

The organisms may be isolated by the inoculation of mineral salt solutions with soil, the nutriment being carbonate and an ammonium salt in the case of *Nitrosomonas* and *Nitrosococcus* and carbonate and nitrite for *Nitrobacter*. Isolation by the usual pour plate pure culture methods is difficult if not impossible, but colonies may be secured by inoculating silica gel plates from the enrichment cultures. *Nitrosomonas* grows in microscopic, colorless colonies which turn brown on continued incubation, while *Nitrobacter* produces somewhat larger colonies, light brown in color.

The oxidation of ammonia is brought about not by a single species of bacterium but rather by a group of closely related organisms. *Nitrosomonas europaea*, found in western Europe, is a coccobacillus about 1.5 by 1.0 μ and exists in two forms, one a zooglea of closely packed cells and the other an actively motile swarming (monas) stage in which each cell has a single flagellum. Morphologically similar organisms have been found in this country and elsewhere, although in some cases one stage appears to predominate over the other to such a degree that some might be taken to be different organisms. Coccus forms, given the generic name *Nitrosococcus*, have also been isolated in various parts of the world. A number of species have been reported which some workers group under the single head of *Nitrosococcus nitrosus*. These organisms are all gram-positive, obligate aerobes. The nitrite oxidizing organisms appear to be somewhat more homogeneous. All are rod-shaped, 1.0 by 0.3 to 0.4 μ in size, with one or both ends pointed, non-motile and gram-negative or gram positive. Neither *Nitrobacter* nor the ammonia oxidizing organisms form spores.

The Sulfur Bacteria. The group of autotrophic bacteria that derive their energy from the oxidation of sulfur and its compounds is, both morphologically and physiologically, somewhat more complex than that comprising the nitrifying organisms. Some of the organisms, the filamentous forms, are more closely related to the lower fungi than are the so-called "true bacteria." *Beggiatoa*, one of the common forms, shows a close resemblance to the blue-green alga *Oscillaria*. Others, such as *Thiobacillus*, are morphologically indistinguishable from the usual bacteria. In all, three morphological groups may be observed:

- (1) The thread forming, filamentous forms usually regarded as "higher bacteria" which accumulate sulfur granules within the cells. Three genera are ordinarily included in this group: *Beggiatoa*, *Thiothrix* and *Thioploa*.
- (2) Non thread forming organisms existing in a number of forms and including such genera as *Thiobacillus*, *Thiospirillum*, *Thiovulum*, *Achromatium*, etc. *Thiobacillus* is often separated from the other organisms on the basis of the failure to accumulate sulfur granules within the cells.
- (3) The purple and green sulfur bacteria, which differ from the other two groups in that they are pigmented, the pigments making possible a photosynthetic metabolism.

The sulfur bacteria are widely distributed over the earth and are commonly found in the water of sulfur springs, in sewage-laden streams, in swamps where masses of vegetable matter are undergoing slow decomposition and, in fact, wherever sulfur and hydrogen sulfide are present. Whether such organisms bear any relation to the laying down of sulfur deposits is uncertain. It has been suggested that possibly gypsum deposits may have

Bennett and Stokes (1952) of an outbreak in an orphanage lasting over a period of 8 years supports the view that close contact with faecal material is the common mode of infection. The clinically manifest disease was almost completely confined to a group of student nurses. These became infected from the infants and children among whom there was a continual series of anicteric cases. The institution of a nursing technique designed to reduce the risk of infection from the faeces brought the outbreak in the nurses to an end, even though no steps were taken to control infection by the respiratory tract. The pathogenesis of the disease is by no means clear, and it may be that some activating factor, such as that met with in infectious hepatitis of mice (see p. 2211), is necessary to enable the hepatitis virus to produce its full effect.

Though various animals, such as pigs, mice, rats, and canaries, are said to have been infected experimentally (see Andersen and Tulinius 1938, Dresel and Weineck 1950, Wildfuhr 1951), no satisfactorily reproducible results have been obtained by this means. Most of our knowledge about the infective agent has been derived from transmission experiments on human beings. These have shown that volunteers can be infected with faeces or blood taken during the first few days of the disease, but not with pharyngeal secretions or with urine (Voegt 1942, Cameron 1943, MacCallum and Bradley 1944, Neefe and Stokes 1945, Havens 1946a, Report 1951b). An exception may perhaps be made for urine, which Findlay and Willcox (1945) found to be infective in natives suffering from bilharziasis. The agent, which is sometimes referred to as Virus A, can pass through a Seitz filter, and proves infective by subcutaneous injection as well as by the mouth (Cameron 1943, Neefe and Stokes 1945, Findlay and Willcox 1945). The incubation period after oral infection is the same as in the natural disease, namely 15-40 days.

Early attempts to cultivate the virus proved a failure; but W. Henle and his colleagues (1950) reported success by the inoculation of serum and of filtered stools from cases during the acute stage into tissue cultures of rabbit liver cells in roller tubes and minced chick embryos in Simms-Sanders medium followed by passage through the amniotic cavity of the chick. Strains were isolated from two separate outbreaks, and reproduced an anicteric form of the disease in human volunteers infected by the mouth after an average incubation period of 24 days (Drake *et al.* 1950). Confirmation of these results is still awaited.

Apart from exclusion of a known pathogenic agent and of Weil's disease, bacteriology can be of little help in the diagnosis of infective jaundice. Though there may be a transient leucocytosis in the early stage of the disease, leucopenia is the rule. There is a rise in the relative proportion of monocytes, but less than that in glandular fever. The blood picture alone is often of value in the differential diagnosis from Weil's disease, in which there is a polymorphonuclear leucocytosis. No specific complement-fixation test has yet been worked out (Miles 1946). G. Henle and her colleagues (1950) described a skin test with an antigen prepared by irradiation of infected amniotic fluid. The test is positive in about half the cases during the course of the disease, and in 90-100 per cent. of persons who have recovered from it. Its value therefore appears to lie more in indicating the existence of immunity to the disease than in diagnosis of an actual attack (Bennett *et al.* 1952). The virus resists heating at 55° C for over 1 hour, but can be destroyed under certain conditions by ultraviolet irradiation. In water it survives chlorination with 1 p.p.m. of chlorine for over 30 minutes, but is attenuated by 15 p.p.m. (Neefe *et al.* 1945).

resulted from the microbial oxidation of sulfur to sulfate neutralized by calcium salts present in the earth.

The Sulfide Bacteria. The oxidation of sulfur compounds by these organisms proceeds through a series of stages. The so-called "sulfide bacteria," including the filamentous forms, derive their energy primarily through the oxidation of hydrogen sulfide to elementary sulfur, which is deposited as granules within the cells:

The reaction is the energy-yielding process of these organisms. If the supply of hydrogen sulfide runs low, the organisms further oxidize the accumulated sulfur to sulfate.

The Thionic Acid Bacteria. A second physiological group, called the thiosulfate or thionic acid bacteria, obtains its energy primarily through the oxidation of thiosulfate, though some members are capable of oxidizing elementary sulfur. The obligate autotrophs, *Thiobacillus thioparus*, is included in this group, together with *Thiobacillus denitrificans*. Some strains of the latter have been found to be obligate autotrophs and also obligate anaerobes, growing in the presence of nitrate, while other strains are both facultative autotrophs and facultative anaerobes. *Thiobacillus thioparus* accumulates free sulfur outside of the bacterial cells when grown in thiosulfate media and the oxidation is supposed to proceed thus:

This organism is also able to oxidize sulfide and tetrathionate but oxidizes elementary sulfur to sulfate only very slowly. A number of common enteric bacilli, however, are able to reduce tetrathionate.

The oxidation of sulfur and reduction of nitrate by *Thiobacillus denitrificans* growing under anaerobic conditions proceeds either as:

or, in the presence of calcium carbonate, as.

The organism is able to oxidize thiosulfate anaerobically in the presence of nitrate according to the following reaction.

The Sulfur Bacteria. A third group, the sulfur bacteria, is represented by only one species, *Thiobacillus thiooxidans*, which derives its energy primarily through the oxidation of elementary sulfur to sulfate. It is also able to oxidize thiosulfate to sulfate, both oxidations proceeding as indicated above. This strictly autotrophic organism is remarkable for its tolerance of high acidities. Sulfuric acid accumulates in its cultures as a result of the oxidation of sulfur, and normal growth takes place in concentrations as high as 0.25 molar, and even 0.5 molar does not completely inhibit growth. Although a strict auto-

(Lehane *et al.* 1949). Calculations indicated that at least 0.35 per cent. of donors must have been carrying the icterogenic virus.

The incubation period of serum hepatitis is usually 2-5 months. The morbidity is often high. In some outbreaks the case-fatality rate has been negligible; in others it has been considerable. There is at present little evidence to suggest that serum jaundice is contagious. Experiments on human volunteers have shown that the serum of patients suffering from the disease can give rise to jaundice on subcutaneous injection, and that the infective agent is present in the blood during the latter part of the incubation period, during the acute stage, but not usually during convalescence (Oliphant *et al.* 1943, Havens 1946*b*), though it has been demonstrated in the blood for as long as 5 years after an attack (Report 1953*a*). The virus, which is sometimes known as Virus B, does not appear to be present in the stools, nor can infection be transmitted by the oral route. Filtration experiments show that it can pass through a gradocol membrane of A.P.D. 52 μ , suggesting that it is probably not more than 26 μ in diameter (see Report 1953*a*).

Relationship of serum hepatitis to infectious hepatitis.—Opinion is divided on the relationship between these two diseases. The general symptomatology, the changes in the white cells of the blood, and the primary necrosis of the liver are all compatible with the view that they are caused by the same infective agent (see Dible *et al.* 1943, Sheehan 1944). Moreover, the causative agent of both diseases is fairly heat resistant, withstanding a temperature of 56° C. for at least 1 hour. On the other hand, there are several differences between them, some of which are dependent on the different methods of transmission (Table 179).

TABLE 179

DIFFERENCES BETWEEN INFECTIOUS HEPATITIS AND SERUM HEPATITIS.

Infectious Hepatitis	Serum Hepatitis
1. Contagious	Apparently not contagious
2. Incubation period 15-40 days	Incubation period 60-160 days
3. Onset acute	Onset insidious
4. Febrile course	Little or no fever
5. Affects children and young adults	Affects all ages
6. Commonest in autumn and winter	Occurs all the year round
7. Virus present in stools	Virus apparently not present in stools
8. Disease experimentally transmissible by mouth	Disease not experimentally transmissible by mouth
9. One attack confers some immunity to infectious hepatitis but not to serum hepatitis	One attack confers some immunity to serum hepatitis, but not to infectious hepatitis
10. Skin test with hepatitis virus positive . .	Skin test with hepatitis virus negative

It may be added that an attack of serum hepatitis not only fails to confer immunity against infectious hepatitis but actually seems to predispose to it (Gauld 1947). None of these differences by itself is conclusive evidence that the two viruses are distinct. The longer incubation period of serum hepatitis, for example, may result from partial neutralization of the virus by antibodies in the serum of the donor or recipient (Aycock and Oren 1947). The failure of cross-immunity may be ascribable to differences in antigenic constitution, and the non-pathogenicity of the serum hepatitis virus by the mouth to differences in virulence. The balance of opinion perhaps favours the dualistic conception (Report 1953*a*); but this leaves us with the problem of deciding how serum jaundice is normally propagated in the absence of parenteral injection. Since, moreover, it is known that parenteral

The Sulfur Bacteria

trophe, *Thiobacillus thiooxidans* is not so sensitive to the presence of organic matter as are some other autotrophes. The work of Vogler and of Umbreit has clarified the mechanism whereby the energy released in the oxidation of sulfur to sulfate is used for the assimilation of carbon dioxide into organic compounds. The oxidation of sulfur in the absence of carbon dioxide is accompanied by the uptake of inorganic phosphate and the formation of ATP. If then carbon dioxide is supplied to the bacteria, even in the absence of oxygen, carbon dioxide is rapidly assimilated and inorganic phosphate is liberated. It thus appears that the energy released in the oxidation of sulfur is stored in the energy-rich bonds of ATP, in which form it is used in the fixation of carbon dioxide into organic compounds. This mechanism for energy transfer is the same as that found in heterotrophic bacteria.

In the absence of sulfur, *Thiobacillus thiooxidans* oxidizes an endogenous polysaccharide. LePage and Umbreit¹⁸ have found that this polysaccharide is metabolized via a series of phosphorylated intermediates identical with those occurring in heterotrophs, and O'Kane has established that this bacterium can carry out the autotrophic synthesis of thiamine, riboflavin, nicotinic acid, pantothenic acid, pyridoxine and biotin, all growth factors for heterotrophic bacteria and higher organisms.

It would seem that the metabolism of this autotrophe, and perhaps others as well, might be divided into two phases. In the first, carbon dioxide is fixed and transformed into a few reactive organic compounds by the use of the energy obtained from the oxidation of inorganic substances or from light (in the case of the photosynthetic forms). This would be a unique and distinctive portion of autotrophic metabolism. In the second phase, these few metabolically active substances are used in the synthesis of cellular material by processes comparable to those occurring in heterotrophs.

Although the influence of light on the metabolism of the purple and green sulfur bacteria had been suspected for some time, it was not until 1941 that the photosynthetic character of these microorganisms was first demonstrated through the work of van Niel.¹⁹ The green sulfur bacteria, strictly anaerobic conditions in the presence of hydrogen sulfide and carbon dioxide. In the absence of oxidizable sulfur compounds, green sulfur bacteria will develop in the presence of organic compounds, which are metabolized under conditions. As in plants, photosynthesis in bacteria is accompanied by an oxidation-reduction process, and may be represented by the following equation:

It is to be noted that in the case of green plants, the process of photosynthesis is accompanied by the oxidation of hydrogen sulfide, resulting in the formation of elemental sulfur. In the absence of hydrogen sulfide, green plants are unable to grow.

¹⁸ LePage, Arch. Biochem. 1942, 25 617.
¹⁹ See the references for van Niel, J. Biol. Chem. 1941, 137 113.

least 15 months. It can be grown on the chorio-allantoic membrane of the developing chick embryo. It differs from the virus of infectious hepatitis and from the mouse hepatitis virus described by Gledhill and Andrewes (see below).

INFECTIOUS HEPATITIS IN ANIMALS

Hepatitis of viral origin seems to be not uncommon in animals. Among dogs and mice we know that the disease may be widely spread under natural conditions, and there is reason to believe that the same may be true of certain other animals.

Infectious hepatitis of Dogs.—Rubarth (1947) described an infectious hepatitis of dogs that appears to be widespread in Sweden. The disease is sometimes known by his name. All breeds are affected, but terriers seem to suffer most. Susceptibility is greatest just after weaning. The clinical picture is one of apathy, anorexia, thirst, diarrhoea and vomiting, fever and occasionally convulsions; jaundice is uncommon. The disease, which is contagious, ranges in severity from the acute fulminating type with death in 24 hours to a completely symptomless infection. On the whole, the case-fatality rate seems to be low. *Post mortem* in fatal cases hepatitis and splenitis are found with increase of fluid in the peritoneal cavity and subcutaneous tissues. Histologically, Rubarth reported the presence of intranuclear inclusions in the liver cells and in the vascular endothelium. He prepared a freeze-dried antigen from the liver which fixed complement with the serum of affected dogs. From the fact that 70 out of 100 dogs of various ages contained complement-fixing antibodies in the blood, he concluded that the disease was very common but was not usually diagnosed. He was able to reproduce the disease by the intraperitoneal inoculation of liver, serum or peritoneal fluid into susceptible puppies, but not into laboratory animals; the incubation period of the experimental disease was 3 days. Liver suspensions were still infective after Seitz filtration. Rubarth's observations have been generally confirmed by workers in other countries (see Parry *et al.* 1951). Miles and his colleagues (1951), who studied an outbreak in Great Britain, described the cultivation of the infective agent in the yolk sac of fertile eggs with reproduction of the disease in dogs after 12 successive passages. Recovery from the natural disease is followed by immunity lasting for at least a year. No satisfactory form of treatment is yet known.

Encephalitis of Foxes.—We include here a disease which according to Rubarth (1947) is caused by a virus closely allied to, if not identical with, infectious hepatitis of dogs. Encephalitis of foxes is endemic in certain parts of the United States, and at times assumes epidemic proportions. It is caused by a filtrable virus which invades the blood, probably through the respiratory mucosa, and may be demonstrated in various tissues. Clinically the disease is characterized by anorexia, hyperexcitability or lethargy, convulsions, paralysis, and not infrequently by death. Pathologically, hæmorrhages in the brain and cord and in the viscera constitute the most striking feature of the disease; perivascular infiltration with round cells is common in the cerebral nervous system, and the meninges are usually involved. Characteristic intranuclear inclusion bodies are found in the ependymal and endothelial cells of the central nervous system. The disease can be reproduced by intramuscular, intranasal, or intracranial inoculation of young foxes with homogenized brain and spinal cord. Unlike the natural disease, which seldom has a case fatality exceeding 20 per cent., the experimental disease is fatal in about 70 per cent. of cases. Infection can also be transmitted to dogs,

systems. It is suggested by van Niel that the photochemical decomposition of water is the light reaction, while the reduction of carbon dioxide is a dark reaction. The green pigment, known as *bacteriochlorin* or *bacteriochlorophyll*, is a pyrrol pigment with a porphin nucleus containing magnesium, and it is closely related to, though not identical with, green plant chlorophylls *a* and *b*.

A group of organisms known as the non-sulfur purple bacteria contain *bacteriochlorophyll* and are photosynthetic, but differ from the purple sulfur bacteria in that the reduction is coupled only with the oxidation of organic matter, i.e., they are not facultative autotrophes. They are, therefore, intermediate between the sulfur forms and non-photosynthetic bacteria with a typical oxidative metabolism. Available information concerning them has been reviewed by van Niel.²⁰

The bacterial oxidation of sulfur and its compounds is of considerable importance in the processes involved in the maintenance of the sulfur cycle. As in the case of nitrogen, many bacteria are capable of reducing sulfur—the evolution of hydrogen sulfide from decomposing organic matter reflects the widespread reduction of sulfur in lieu of oxygen under anaerobic conditions—but only a few are able to oxidize it. These organisms assume considerable practical significance at times, producing corrosion of metals laid in sulfur-containing clay soils²¹ and are sometimes responsible for the disintegration of stone and mortar.²²

The relative simplicity of the respiratory mechanisms of the sulfur bacteria is in itself of no small general physiological interest, but equal importance attaches to the fact that these organisms appear to constitute a link between the autotrophic organisms and those dependent upon preformed organic matter through the species that are facultatively autotrophic. Their efficiency is of the same order as that of the nitrifying bacteria, i.e., 5 to 8 per cent of the energy made available through the oxidation of sulfur and sulfur compounds is utilized in synthesis of cell substances.

The Iron Bacteria. Certain of the filamentous bacteria are characterized by deposits of ferric hydroxide in the sheath surrounding the filament or, sometimes, within the cell itself. It was early suggested that these organisms are able to oxidize ferrous to ferric iron and utilize the energy so liberated. It appears, however, that although some of the so-called iron bacteria are obligate autotrophes which are dependent upon the oxidation of iron as a source of energy, the presence of ferric hydroxide is not necessarily indicative of an autotrophic metabolism. One species, *Spirillum ferrugineum*, is an obligate autotrophic organism which grows in inorganic solutions containing ferrous carbonate. The oxidation proceeds according to the following reaction:

The reaction is exothermic but the energy yield is small, about 15 calories per mol, and large amounts of ferrous salt must be oxidized. Starkey²³ has shown that the oxidation of 55.8 gm. of iron as ferrous carbonate produces 106.8 gm.

lamb, lamb to lamb, and lamb to mouse by the bites of mosquitoes of the *Eretma. podites chrysogaster* group. The period taken for the mosquitoes to become infectious when kept at 30° C. was 19-20 days.

Experimentally the disease can be transmitted to susceptible animals, including mice, monkeys and ferrets, but not guinea-pigs or rabbits, by cutaneous, subcutaneous, or intranasal inoculation. Mice are peculiarly susceptible, most of the animals dying in 36-96 hours after inoculation (Findlay 1932). By continued passage through the mouse's brain a neurotropic variant of the virus was developed (Mackenzie *et al.* 1936).

The virus is widely distributed in the body, and can pass through the placenta to the foetal organs. Its probable size is 23-35 m μ (Broom and Findlay 1933). In blood it is destroyed by exposure to a temperature of 56° C. for 40 minutes, but it survives contact with 0.5 per cent. phenol at 4° C. for 6 months. In blood serum kept in the refrigerator it remains alive for at least 2 years; such stability is probably unique (Smithburn *et al.* 1949b). It can be cultivated in a minced chick embryo medium (Mackenzie 1933). An attack of the disease confers a high degree of immunity in sheep, and the serum of convalescent animals and human beings contains strong neutralizing and complement-fixing antibodies. Mice can be successfully immunized by a virus treated with formol or inactivated photo-dynamically with methylene blue (Mackenzie 1935).

YELLOW FEVER

Little was known about the ætiology of this once-dreaded disease till the studies of the American and the French Commissions were undertaken in the early years of this century.

The American workers, Reed, Carroll, Agramonte and Lazear (1900-01), at the beginning of the century, first showed that the blood of patients was infective during the first 3 days of the fever; that the infecting agent was able to pass through a Berkefeld filter; that the virus was destroyed in the blood by heating to 55° C. for 10 minutes; that infection was not spread by contagion; that mosquitoes, *Aedes aegypti* (also called *Aedes argenteus*, and *Stegomyia fasciata*) fed on patients during the first 3 days of the fever, became, after an interval of about 12 days, capable of transmitting the disease to normal persons; and that by the suppression of these insects, yellow fever could be brought under control.

Marchoux, Salimbeni and Simond (1903), likewise working with human volunteers, largely confirmed these results. They found, moreover, that the serum of patients during the first 3 days of the fever, but not later, proved infective to normal persons when injected subcutaneously in a dose of 0.1-1.0 ml.; that defibrinated blood kept at 24°-30° C. under a vaseline seal remained infective for 5, but not for 8 days; that the injection of blood kept for 8 days under these conditions was apparently able to produce some degree of immunity in human beings; and that the serum of convalescent patients appeared to be endowed with both prophylactic and therapeutic properties.

The natural outcome of these findings was to undertake an intensive anti-mosquito campaign. The result of this so far exceeded expectations that yellow fever was apparently wiped out of Central and South America. For a time it was believed that the only serious remaining focus of infection was in West Africa. Further work, however, carried out to a considerable extent under the auspices

of ferric hydroxide but only 0.209 gm. of organic cell material, and points out that it is difficult to establish with certainty the reactions whereby the bacteria precipitate the hydroxide. Some of the iron bacteria are also capable of oxidizing manganese salts and precipitate manganese hydrates in their cells.

Other iron bacteria, however, can live without iron and are able to utilize either ferrous carbonate or soluble iron salts of organic compounds. Still others use organic iron compounds but not inorganic iron salts. Harder²⁴ divides the iron bacteria into three physiological groups.

(1) Those, such as *Spirophyllum ferrugineum*, that precipitate ferric hydroxide from solutions of ferrous carbonate and use the carbon dioxide liberated and the energy produced during the oxidation for their life processes (obligate autotrophes),

(2) Those, such as *Leptothrix ochracea*, that do not require ferrous carbonate but that cause the deposition of ferric hydroxide when either inorganic or organic iron salts are present (facultative autotrophes), and

(3) Those, probably including a number of the lower or ordinary water and soil bacteria, that attack organic iron salts, using the organic acid radical as food and precipitating ferric hydroxide or basic ferric salts, which are gradually changed to ferric hydroxide (heterotrophes).

The best known of the iron bacteria are the *Spirophyllum* and *Leptothrix* species indicated above and *Crenothrix polyspora*. These organisms sometimes grow in the conduits of certain public water supplies, where they form unpleasant-looking, brownish, flocculent masses, often leading to complete stoppage of the pipes. The frequent appearance of detached portions of the growth in tap water may give rise to consternation among the water consumers, as in the famous "water calamities" in Berlin, Lille, Rotterdam and other places. There is no evidence that such organisms are directly harmful.

There seems little doubt that iron-depositing bacteria have played an important part in the formation of iron ore deposits, but the relative share of chemical and biological processes in an individual case can be determined only by a thorough study of conditions at the time of deposition, especially as regards sedimentation, climate, depth of water, nature of material in solution and other factors.²⁴

The Oxidation of Hydrogen. The bacterial oxidation of hydrogen has already been indicated in the case of the oxidation of hydrogen sulfide to elementary sulfur. Other organisms, given the generic name *Hydrogenomonas*, are, however, facultative autotrophes which depend upon the oxidation of hydrogen as a source of energy when grown under autotrophic conditions. The hydrogenase is not formed in organic media, but the bacteria grown in inorganic solutions respire with both hydrogen and organic compounds as substrates, suggesting that the hydrogen-oxidizing catalytic system is independent of the normal respiratory process.²⁵

The first of these organisms was described in 1906 by Kaserer and named *Hydrogenomonas pantotrophia*. Other species were described later, such as *Hydrogenomonas vitrea* and *Hydrogenomonas flava*. The oxidation of hydrogen:

the disease for the rest of their lives. It was shown that the bite of a single mosquito was sufficient to produce a fatal infection in a monkey. The virus in the circulating blood of monkeys was able to pass through Berkefeld V and N, but not through W, candles.

After subcutaneous inoculation of a monkey with infective material, there is an incubation period of 3 to 4 days, followed by a rise in temperature of about 3° F.; this temperature persists for 36 to 48 hours, and then falls suddenly to subnormal; collapse occurs, and the monkey dies about 5 to 6 days after inoculation. *Post mortem*, jaundice is usually present in some part of the body, especially the laryngeal mucosa and the subcutaneous fat; small hæmorrhages are frequently found, particularly in the lungs and alimentary canal, and in the wall of the stomach; dark coffee-ground material is often seen in the stomach and small intestine; the most constant feature, however, is the pale, mottled liver, which microscopically shows fatty degeneration and mid-zonal necrosis. The liver, when fresh, is highly infective for monkeys—in a dose of about 0.000,02 gm. When frozen, the liver remains virulent for about a fortnight; when dried and frozen, it remains virulent for about 3 months (Hindle 1929). This forms a very useful method of preserving the virus. The blood of infected monkeys contains enormous quantities of virus, proving infective sometimes in 1/50–1/100 million.

White mice are also susceptible to infection (see Theiler 1930, Dinger 1931). The intracerebral inoculation of these animals with 0.05 ml. of infective blood from a rhesus monkey gives rise, after an incubation period of 5 or 6 days, to an illness characterized by ruffling of the coat, inactivity, photophobia, paresis of the hind legs, tonic and clonic contractions of the whole body, and finally coma and death in 6–9 days. *Post mortem* there is an acute encephalitis, often with dilatation of the skin vessels, swelling of the lymph glands, hæmorrhages into the stomach, erosion of the gastric mucosa, fatty degeneration of the liver, and enlargement of the suprarenals. Infection can be carried on indefinitely by cerebral passage. According to Findlay and Clarke (1935a), an encephalitis may be set up in both monkeys and mice by the intranasal instillation of a neurotropic strain of virus (see also Findlay and Stern 1935). Guinea-pigs can be infected intracerebrally, provided a neurotropic strain is used (Dinger *et al.* 1930, Mathis 1934, Lloyd and Mahaffy 1935).

Properties of Virus.—Yellow fever is caused by a filtrable virus. Its reported diameter by the gradocol membrane technique is 17–28 μ (Findlay and Broom 1933), and by the ultra-centrifuge technique 12–19 μ (Pickels and Bauer 1940) or 29–31 μ (Polson 1954). Its successful cultivation in mouse embryo tissue was reported by Lloyd, Theiler and Ricci (1936). Jadin (1937) grew it on the chorio-allantoic membrane of hens' eggs; and Elmendorf and Smith (1937) simplified this procedure by direct inoculation of the virus into the chick embryo. When grown for several generations in tissue cultures, its virulence becomes modified; it no longer gives rise to a fatal disease when injected into monkeys subcutaneously, but it remains capable of killing mice inoculated intracerebrally (see Theiler and Smith 1937). Other changes can be produced by animal passage (see Sawyer *et al.* 1930, Findlay and Clarke 1935b, Findlay and MacCallum 1938b). No antigenic differences have been recognized among strains of different origin. The virus contains a soluble antigenic material, which may be demonstrated as a precipitinogen in the serum of monkeys during the height of the illness (Hughes 1933). Survival of the virus in infected blood has already been referred to (see also Sawyer *et al.* 1929). It is killed by heat at 55° C in 5 minutes, and rapidly dies in saline suspensions. In tissue, however, that is frozen solid, it remains alive for some weeks, and in tissue that is frozen and dried it retains its viability for years. It

yields relatively large amounts of energy (34.2 Cal. per gram as contrasted with 4.1 Cal. per gram of starch) and, although it cannot be accurately measured, the free energy efficiency of these organisms appears to be somewhat higher than that of the other autotrophes, i.e., 10 to 20 per cent.

It has been suggested that all the hydrogen is not burnt directly by these organisms but that a part of it is converted to formaldehyde, which may in turn be either oxidized or used for synthesis.

Although most of the hydrogen bacteria are obligate aerobes, some are able to grow anaerobically in the presence of nitrate.

As in the case of the oxidation of iron, the oxidation of hydrogen is not confined to a few species of strict autotrophes, and it has been found that a wide variety of well known heterotrophic bacteria oxidize hydrogen in their respiratory process, as pointed out earlier.

The Oxidation of Carbon Monoxide. The bacterial oxidation of carbon monoxide, comparable in many respects to the oxidation of hydrogen, was reported by Beijerinck and van Delden.²⁶ These workers isolated an organism which they named *Bacillus oligocarbophilus*, an obligate autotrophe which grew in the absence of organic carbon compounds and obtained its nitrogen from ammonia, nitrite or nitrate. It was later shown that this organism derived its energy through the oxidation of carbon monoxide to carbon dioxide.²⁷

HETEROTROPHIC BACTERIA

It is seldom if ever possible to draw sharp lines of demarcation in biology, and the separation of bacteria into autotrophic and heterotrophic forms being no exception, it must necessarily be to some degree dogmatic. It has already been pointed out that some of the sulfur, iron and hydrogen bacteria are facultative autotrophes, i.e., that they may live by oxidation of either inorganic or organic compounds. Such forms may well be regarded as connecting links between the two physiological types. A somewhat different kind of interconnection is the sharing, between obligate autotrophes and obligate heterotrophes, of common metabolic mechanisms, such as the utilization of gaseous hydrogen, the assimilation of carbon dioxide and the phosphorylation of carbohydrates. Clearly, then, the distinction between the two physiological types is not a sharp one even though the concepts autotrophe and heterotrophe remain extremely useful.

CARBOHYDRATE METABOLISM

Carbohydrate is the chief energy source for almost all heterotrophic bacteria, The functional equivalence of both aerobic and anaerobic metabolism of

²⁶ Beijerinck and van Delden: *Centralbl. f. Bakt.*, 1903, Abt. II, 2:33.

²⁷ Distilled water standing in the laboratory for long periods may acquire immunologic properties presumably owing to the growth of bacteria. Organisms able to develop on ammonia and carbon monoxide absorbed from the laboratory air may, in some cases, account for such growth on distilled water, a medium which might be supposed to be entirely lacking in nutriment.

passage through the mouse's brain, together with human serum. An attenuated mouse passage virus, without serum, was recommended by Sellards and Laigret (1932, 1936); but though it has been used extensively on African natives, it has been generally regarded as too dangerous for human use. The vaccine developed by Peltier (1917), which is prepared by drying mouse brains infected with a neurotropic strain of yellow fever virus, is open to the same criticism; large numbers of cases of encephalitis followed its use in Eastern Nigeria, many of them fatal.

Much the most satisfactory vaccine so far produced is one made with the variant strain, 17D. This was developed by American workers by growth of the virus in tissue culture containing first mouse embryonic tissue, then whole chick embryo, and finally chick embryo from which the brain and cord had been removed. This strain was found to be greatly attenuated, failing to kill monkeys inoculated either subcutaneously or intracerebrally, and producing fatal encephalitis in mice after an average incubation period of 8 instead of 6 days; it still, however, retained its antigenic potency. Large quantities of vaccine could be prepared by inoculation of the variant strain into the developing chick embryo, incubating the eggs for 3-4 days, grinding up the embryo, suspending it in human serum, and clearing, freezing and drying the resulting mixture. For use the dried virus was rehydrated. The dosage for man was calculated according to the number of mice dying after intracerebral inoculation (Theiler and Smith 1937, Smith *et al.* 1938, Bugher and Smith 1944). This vaccine has been widely used, with excellent results. In the early days occasional batches gave rise to jaundice, coming on as a rule 6 weeks to 4 months after inoculation (see Fox *et al.* 1942b). During the 2nd world war no fewer than 28,585 cases of jaundice occurred in the U.S. Army between January and July, 1942, out of about $2\frac{1}{2}$ million troops inoculated; 62 of these cases proved fatal (Report 1942a, b). There is little doubt that the jaundice was due, not to the yellow fever virus, but to the human serum used in the preparation of the vaccine (see p 2207). Hargett, Burruss and Donovan (1943) later prepared a similar vaccine from which the serum was omitted. No jaundice has so far followed the use of this "aqueous base" vaccine; though Fox and his colleagues (1942a) recorded a number of encephalitic reactions among those inoculated, which they attributed to variation in the 17D strain itself. Kept in the ice-chest the desiccated 17D chick embryo vaccine remains active for at least a year. Judged by the persistence of neutralizing antibodies in the serum, immunity following vaccination lasts for at least 5 years (Anderson and Gast-Galvis 1947). The danger that vaccinated persons may serve to infect mosquitoes seems to be negligible, partly because the concentration of virus in the blood is very low, and partly because mosquitoes artificially infected with modified viruses of this type are unable to transmit the disease to susceptible animals (Roubaud *et al.* 1937, Smith *et al.* 1938, Whitman 1939). For an account of the aetiology, epidemiology and prevention of yellow fever, the reader is referred to articles by Sellards (1941), Russell (1941) and Gordon (1941) and to the authoritative monograph by Strode and his colleagues (1951).

DENGUE FEVER

Dengue fever is a disease of warm climates, and is peculiar to man; it occurs during the summer months, often in severe epidemic form, attacking a high proportion of the exposed population, and it is followed by a comparatively short-lived

carbohydrate was first recognized by Pasteur, and it is now evident that, although bacteria form many substances from carbohydrate, the breakdown of carbohydrate proceeds in general along well defined pathways, and variations among species are not so great as was once thought. The chief modes of carbohydrate breakdown are summarized in the accompanying diagram.

CARBOHYDRATE BREAKDOWN IN BACTERIA

Breakdown of Oligosaccharides and Polysaccharides. Some *Pseudomonas* species can rapidly oxidize lactose and maltose to the corresponding aldobionic acids,²⁸ but most bacteria split compound sugars to their component monosaccharides before they are further metabolized. Oligosaccharides and polysaccharides may be hydrolyzed by the addition of a molecule of water to each glycosidic linkage. The hydrolysis of a compound sugar is an irreversible reaction and proceeds with the liberation of energy, but the energy yield is very small in comparison with that made available through oxidation of the component monosaccharides. Bacteria contain enzymes which are capable of hydrolyzing a wide variety of polysaccharides and oligosaccharides.

Cellulose.²⁹ Although cellulose is the most widely distributed polysaccharide in nature, the ability to bring about its decomposition is possessed by only a few organisms. The enzyme cellulase is found in a few higher organisms, some snails and a few marine forms, but even the herbivorous animals are dependent upon the presence of cellulose-decomposing microorganisms in the intestine for

²⁸ Stodola and Lockwood: *Jour. Biol. Chem.*, 1947, 171 213.

²⁹ See review by Waksman: *Bot. Rev.*, 1940, 6 637.

antigenic types of virus, and that immunity is restricted to the homologous type (Sabin 1952, Meiklejohn *et al.* 1952).

In the diagnosis of dengue the severe leucopenia, with a proportional increase in the immature granulocytes, is of help. According to Hotta (1952) a skin reaction can be elicited from the 2nd day onwards by the intradermal injection of an antigen prepared from infected mouse brain. (For a general account of the disease, and of the investigations carried out during the 2nd world war, see Simmons 1941, Lumley 1943, Yaoi and Arakawa 1948, and Sabin 1952.) In control of the disease, the usual measures against mosquitoes should be employed.

SANDFLY FEVER

SYNONYM: Phlebotomus Fever.

This disease occurs in tropical and sub-tropical countries. It is characterized by an incubation period of 1-6 days, and a fever lasting at least 3 days, accompanied by severe headache, pains in the back, bones, joints, and muscles, and followed by considerable prostration. It is rarely fatal. Second, and even third, attacks do occur, but are not very common. The causative agent appears to be a filtrable virus. There is, however, some discrepancy of opinion on its properties. For instance, Shortt and his colleagues (1938) find that it is about 160 μ in diameter, and that it can be grown in a tissue culture medium containing minced chick embryo, human serum and chick plasma, and on the chorio-allantoic membrane of the developing chick embryo (Shortt, Rao and Swaminath 1936). Sabin, Philip and Paul (1944), on the other hand, maintain that it is only 20-40 μ in diameter and that it cannot be cultivated by the chorio-allantoic membrane technique. Again, according to Shortt and his colleagues (1940), the virus can be demonstrated in the patient's blood for a week in most cases, and occasionally for as long as 6 weeks. The time during which the serum is infective is given by the American observers as 3 days, namely for 1 day before to 2 days after the onset of the fever. Sera kept in the ice-chest remain virulent for months. As present in human blood, the virus, when inoculated into *rhesus* monkeys, gives rise to a mild fever; but the cultivated virus produces only a symptomless infection (Shortt *et al.* 1940). The incubation period after intracutaneous injection into human beings is said to be 2½ to 6 days (Sabin and Paul 1944). Neutralizing antibodies appear early in the serum of convalescent patients and of inoculated monkeys; they can be demonstrated by monkey protection tests, or by inhibition of the growth of the virus in culture. Immunity is said to persist for at least 4 months. Infection is spread by the sandfly *Phlebotomus papatasi* (see Whittingham 1924), though possibly other species may act as vectors. The flies do not become infective for 7-10 days after biting a patient with the fever. Diagnosis is often difficult. The absence of catarrhal symptoms is of help in distinguishing the disease from influenza, and the absence of rigors from malaria. Skin rashes do not occur (Walker and Dods 1941). The disease may closely simulate lymphocytic choriomeningitis, but the cell count in the cerebrospinal fluid is not increased (Pearson 1941). In the blood there is a leucopenia. Prophylaxis consists mainly in abolishing sandfly breeding grounds, spraying with D.D.T., and in sleeping under a close-mesh net. Dimethyl phthalate and a pyrethrum vanishing cream are said to afford considerable protection against sandfly bites (Sabin and Paul 1944).

the preliminary decomposition of this polysaccharide.³⁰ The breakdown of cellulose and other polysaccharides in nature is an essential part of the decomposition of plant residues and the consequent returning to the atmosphere of carbon dioxide removed through the photosynthetic activities of chlorophyll-containing plants. Relatively few species of bacteria are able to decompose cellulose, but those that do are widely distributed in the soil and the mud of sea bottoms as well as in the intestines of herbivorous animals.

A number of bacteria, both aerobic and anaerobic forms, have been isolated which decompose cellulose actively in pure culture. Perhaps the best known aerobic organism is a spiral form, *Spirochaeta cytophaga*, which occurs in soil in considerable numbers. A large number of other bacteria which bring about the aerobic decomposition of cellulose have been studied, but the identity of many of them is doubtful. The breakdown of cellulose by anaerobic bacteria is ordinarily accompanied by further decomposition of the glucose so formed to hydrogen and methane in some cases and to organic acids and carbon dioxide in others. Some species have been described, such as *Bacillus cellulosa dissolvens*, which was isolated from human feces, but in general these organisms are not well known. Equally obscure are the thermophiles which have been isolated from actively fermenting manure heaps. The decomposition of cellulose in nature is largely, if not entirely, a process brought about by mixed cultures of bacteria.

The hydrolysis of cellulose takes place in two stages: first, a breakdown to the disaccharide cellobiose; and second, the hydrolysis of cellobiose to glucose. These reactions are brought about by two separate enzymes, cellulase and cellobiase respectively, and the decomposition, to cellobiose at least, takes place outside the bacterial cell.

Hemicelluloses and Pectins. In addition to cellulose proper, plant tissue contains other polysaccharide material designated as hemicellulose and pectin. On hydrolysis, both yield pentoses, hexoses and uronic acids. Although hemicelluloses are decomposed in nature, largely under the influence of bacteria present in the soil, the chemistry of these compounds is largely unknown and, in consequence, little is known of the processes of their decomposition.³¹

The decomposition of pectin, through the agency of the enzyme pectinase, is brought about by a comparatively small number of species of anaerobic bacteria. The process itself is of considerable commercial importance since these organisms are responsible for the retting of flax and hemp and for the rotting of certain fruits and vegetables. Retting is accomplished by submerging flax and hemp in water and allowing the plant tissue to remain until the dissolution of pectin allows the separation of the fibers.³² The organisms responsible for the decomposition of pectin are closely related to the group of anaerobic soil forms, the amylobacter group, which includes the butyric acid organisms and others. A number of other bacteria, including *Lactobacillus*, *Aerobacillus*, *Micrococcus* and *Enterococcus*, decompose pectins.³³ The nature of the process

convalescent serum is said to be of some value (see Report 1951a, Beard 1952, Andrew 1953). (See also Report 1953b, Powell 1954.)

DISTEMPER

Distemper is an acute infectious disease of young carnivorous animals. It is very common in puppies, and has given rise to great trouble in foxes reared for the fur industry. In the dog the disease is characterized by an incubation period of 3-6 days, an initial coryza, fever of a peculiar type, severe gastro-intestinal disturbance, and catarrhal inflammation of the respiratory tract often passing on to pneumonia. Encephalitis is a less common complication. The disease normally lasts 2-4 weeks and has a low mortality; but complicated cases, which probably constitute 40 or 50 per cent. of all cases, may last for several weeks and are accompanied by a case-fatality rate running up to 80 per cent. The disease is said to be characterized by acute anaemia and hypoglycaemia (Wharton and Wharton 1934).

The nature of the *encephalomyelitis* that is sometimes observed has given rise to a great deal of discussion. Perdrau and Pugh (1930) regarded it as being caused by a virus different from the distemper virus, mainly because of the demyelination that is present. Verluise (1939), however, recognized two types of encephalitis, one caused by the distemper virus itself, and another by a neurotropic virus that was able to produce encephalitis in the absence of distemper. In England, Macintyre, Trevan and Montgomerie (1948) likewise recognized two types of encephalitis caused by a filtrable agent infective for the ferret, namely the distemper virus and the virus of hard pad disease.

In *hard pad disease* the foot pads of the dog become hard and often very thick, usually within a week of the onset of illness. Convulsions and other signs of encephalitis develop. Post-mortem examination reveals demyelination of the cerebellar peduncles, glial proliferation, and weakly acidophilic intranuclear inclusion bodies. A suspension of infective material from hard pad disease injected into the ferret gives rise to a disease resembling distemper, and into the dog merely to a febrile reaction lasting 10-14 days. According to Macintyre and his colleagues animals that have recovered from hard pad disease are not immune to distemper, nor does distemper antiserum protect against hard pad disease.

These conclusions are somewhat at variance with the findings of Australian and American workers (Hurst *et al.* 1943, Koprowski *et al.* 1950), both of whom isolated what appeared to be the true distemper virus from dogs suffering from encephalitis. Demyelinating lesions were found in the cerebellum, and acidophilic, mainly intranuclear, inclusion bodies in the glial cells. Injected into puppies, the virus produced a nervous type of distemper, but in ferrets vaccinated against distemper it produced no disease at all. Mansi (1951), who isolated a strain of virus from a dog suffering from encephalitis in Glasgow, found it to be immunologically identical with the true canine distemper virus and the hard pad virus of Macintyre, Trevan and Montgomerie. He would regard it as a distemper virus endowed with neurotropic affinities. Though it is too early to reach any definite conclusion, it seems probable that the distemper virus has variants, some of which exhibit a special predilection for the central nervous system. Of these, the hard pad virus may be one.

Distemper occurs naturally in the ferret, and is characterized by an incubation period of about 10 days, an initial coryza, and the formation of vesicles and pustules around the mouth; just as in dogs, encephalitis may develop in a small proportion of cases. Distemper in the ferret is a very fatal disease, causing a mortality of about 90 per cent. (Dunkin and Laidlaw 1926). The disease has been studied to a limited extent in the cat (Hindle and Findlay 1933, Dalling 1934), the fitch

of decomposition is obscure, though the sugars resulting from hydrolysis are further decomposed to the usual products of sugar oxidation. Few if any of the pectin-decomposing bacteria are able to hydrolyze cellulose also. The combination of the two properties in a single organism would, of course, result in the decomposition of the flax fibers freed by hydrolysis of the pectin.

Starch. Unlike cellulose, starch may be hydrolyzed by a wide variety of living organisms, and the extracellular enzyme diastase, or amylase, is possessed by many bacteria. Like cellulose, however, starch is hydrolyzed in two stages, first to the disaccharide maltose, and second by a further hydrolysis to glucose. The ability of a given organism to hydrolyze starch has acquired an importance equal to sugar fermentations as a differential character in the study of some bacteria.

Miscellaneous Polysaccharides. A wide variety of gums and mucilaginous substances, polymers designated as pentosans, levans, galactans, and the like according to the nature of the products of their hydrolysis, may be decomposed by bacteria. Polysaccharides of bacterial origin, such as pneumococcus polysaccharide, may be decomposed by other bacteria (p. 394), and bacteria have been found which hydrolyze agar, a polysaccharide resistant to the action of the great majority of bacteria.³⁴

Polymeric Degradation. Leibowitz and Hestrin³⁵ have described a mode of compound sugar degradation which is of wide occurrence in bacteria. For example, *B. subtilis* decomposes sucrose with the liberation of free glucose and the formation of levan, a fructose polysaccharide. This method of sugar breakdown has been termed polymeric degradation and involves the synthesis of a new glycosidic bond at the expense of a previously existing one. The reaction appears to be reversible and may be responsible for the breakdown or synthesis (*vide infra*) of sucrose and polysaccharides.

Phosphorylysis. Polysaccharides and oligosaccharides may also be split, not by the addition of water but by the addition of phosphoric acid instead. Such a cleavage is called phosphorylysis and is catalyzed by a group of enzymes called phosphorylases. The sucrose phosphorylase of *Ps. saccharophila* catalyzes the reaction³⁶.

In contrast to hydrolysis, phosphorylysis of glycosidic bonds is reversible, and compound sugars may be synthesized by the reverse reaction (*vide infra*).

Anaerobic Breakdown of Glucose and Other Hexoses. In most bacteria the first step in the metabolism of the six-carbon sugars is their cleavage to two three-carbon compounds. This process, referred to as either fermentation or glycolysis, proceeds without the intervention of molecular oxygen, although it occurs in many organisms under both aerobic and anaerobic conditions. Strictly speaking, the term *fermentation* is best used to describe all the metabolic transformations of carbohydrate which occur without direct reaction with molecular oxygen, and the term *glycolysis* is best limited to the breakdown of

³⁴ See Stanier, *Jour. Bact.*, 1941, 42:527.

³⁵ For references to original papers, see Barker and Doudoroff, *Ann. Rev. Biochem.*, 1946, 15:497.

given up (Dalling 1932b). If, however, a fully virulent dried ferret virus is inoculated, followed 1-2 hours later by a dose of immune serum, a satisfactory immunity results. This method is extensively used in practice in order to save the veterinarian two visits. For treatment of the disease immune dog serum may be used. It is said to be of considerable value if given within 7 days of the onset of symptoms (Wright 1932). It is also useful for prophylaxis.

INFECTIOUS FELINE AGRANULOCYTOSIS. FELINE ENTERITIS. FELINE PNEUMONIA

A widespread highly contagious disease of cats occurs in the United States to which the name feline enteritis is often given, but for which the term infectious feline agranulocytosis is preferred by American workers. It was studied by Hammon and Enders (1939) and by Syverton and Lawrence and their colleagues (Syverton *et al.* 1943, Lawrence *et al.* 1943). Though the accounts of these observers differ to some extent, there is little doubt that they were dealing with the same disease. Kittens and young cats seem to be mainly affected. The incubation period is 4-7 days. The symptomatology is irregular, but listlessness, prostration, anorexia, vomiting, and diarrhoea are often present. The temperature is raised, and nasal and ocular discharges are common. The most characteristic feature, however, is the occurrence of a profound leucopenia, amounting sometimes to almost complete absence of white cells from the circulating blood. Death usually occurs in 2-4 days. The case fatality is given as 50 per cent. At post-mortem there is little macroscopic evidence of disease; but microscopically there is severe aplasia of the cellular elements of the bone marrow, and conspicuous intranuclear inclusion bodies are found in the epithelial cells of the intestinal mucosa and the reticular cells of the spleen and lymph nodes. Infection is spread by contact with infective discharges. A virus, capable of passing through a Berkefeld W filter, and therefore probably not greater than 35 μ in diameter, can be demonstrated by animal inoculation in the blood, organs, nasal secretion, faeces, and sometimes urine of infected animals. The disease can be reproduced experimentally by inoculation of non-immune animals by the oral, intranasal, subcutaneous, and intravenous routes. Attempts to cultivate the virus have so far failed. The virus is specific for cats, and is apparently distinct from the feline distemper virus, but further observations are required. Recovery from the disease is accompanied by the appearance of specific neutralizing and protective antibodies.

According to Jennings (1947, 1949) feline enteritis is not the same as feline agranulocytosis. Jennings recognizes a third disease—feline pneumonia. Enteritis is said to affect young animals in particular: pneumonia affects cats at all ages. Whether each of these three diseases is caused by a distinct virus is, however, doubtful, and further work is required to clear up the present confusion.

SWINE FEVER

SYNONYMS: Hog Cholera. *Schweinepest* (German). *Peste du porc* (French).

Swine fever or hog cholera is an infectious disease, peculiar to pigs, caused by a filtrable virus. It is widespread throughout the world; a special form of the disease was described by Montgomery (1921) in East Africa. The disease is primarily a septicæmia, but in a large proportion of cases intestinal compli-

cifically, Utter and Werkman⁴⁰ and Still⁴¹ have shown the occurrence of almost all the reactions of the Meyerhof-Embden-Parnas-Cori-Warburg scheme in the fermentations of the coliform bacteria.

While most bacteria convert glucose to pyruvic acid by the same mechanism, they show great diversity in the manner in which they dispose of pyruvic acid once it is formed, thus giving rise to the different types of bacterial fermentations. Under anaerobic conditions, pyruvic acid or one of its derivatives is reduced by accepting electrons, usually from 3-phosphoglyceraldehyde, in a coupled oxidation-reduction reaction.

Lactic Acid Fermentation. The simplest type of fermentation is the lactic acid fermentation in which pyruvic acid itself is the electron acceptor.

The overall equation for the lactic acid fermentation is:

Bacteria of the genera *Lactobacillus* and *Streptococcus* form large amounts of lactic acid from glucose, and some species have an almost pure lactic acid fermentation. In addition, lactic acid is one of the products of glucose fermentation in many other bacteria.

Alcoholic Fermentation. In alcoholic fermentation, pyruvic acid is decarboxylated to acetaldehyde by pyruvic carboxylase (in yeast, a Mg-diphosphothiamine-protein)

The acetaldehyde then functions as the electron acceptor in the oxidation-reduction reaction of glycolysis and is reduced to ethanol.

The overall equation for alcoholic fermentation is:

Some *Sarcina* species carry out an almost pure alcoholic fermentation, and many other bacteria produce small amounts of ethanol from glucose.

Propionic Acid Fermentation. The propionic acid bacteria, which are very closely related to *Lactobacillus*, reduce pyruvic acid all the way to propionic acid. They also decarboxylate pyruvic acid to acetaldehyde and CO_2 .

⁴¹ Still: *Biochem. Jour.*, 1940, 34:1177, 1374.

inactivated with crystal violet. The vaccine, which was developed by McBryde and Cole (1936), consists essentially in the use of defibrinated blood taken from infected animals, and inactivated with crystal violet in a final concentration of 1/2,000; ethylene glycol is added to keep down bacterial contamination (Doyle and Wright 1917). A single dose of 5-10 ml. is given subcutaneously according to the weight of the animal, or a smaller dose by the intradermal route. Immunity develops within a fortnight of injection and remains for at least a year. The vaccine can be used only on healthy herds that are not in contact with infection. In the United States of America a living lapinized or rabbit-adapted vaccine is preferred. Animals that have been exposed to infection may be passively protected by the injection of antiserum taken from convalescent animals. Simultaneous immunization with antiserum and virulent blood is sometimes undertaken to produce an active immunity under cover of a passive.

Baby pigs may suffer from a very contagious form of *infectious gastro-enteritis* caused apparently by a virus different from that of swine fever. According to Bay, Hutchings,

present in the gastric and intestinal mucosa, and the kidneys show degeneration. The incubation period of the disease is 1-4 days. Infection can be transmitted experimentally to new-born pigs by feeding or injection with minimal quantities of ground-up tissues. Even a 1/1,000,000 dilution of a Berkefeld N filtrate may prove infective by the mouth. In filtrates the causative agent is inactivated by heating to 56° C. for 1 hour, and by exposure to 0.5 per cent. phenol for 30 minutes at 37° C.

RINDERPEST OR CATTLE PLAGUE

Rinderpest is an acute infectious disease of cattle, characterized by an incubation period of 3-9 days, acute fever lasting 4-7 days, inflammation of the buccal and gastric mucosa often attended by necrosis and ulceration, a persistent leucopenia, and a case-fatality rate ranging from 15 to 75 per cent. The disease is prevalent in southern Europe, Asia, and Africa where it constitutes a major economic problem. It has been imported from time to time into Great Britain, but has always been successfully eradicated by the slaughter policy. The existence of chronic carriers, with diphtheritic ulcers in the abomasum, was recorded by Gibbs (1933). The disease also attacks buffaloes (Schein 1917).

Inoculation of normal animals with tissue fluids from an infected animal reproduces the disease. At the height of the attack the blood proves virulent in a dose of 1/1,000 to 1/25,000 ml. (Schein 1917). There is evidence that the virus is contained chiefly within the leucocytes. Thus in blood that is allowed to clot naturally the serum is avirulent; in defibrinated blood that is centrifuged the deposit alone is virulent; in blood laked with distilled water and centrifuged, the deposit, which consists mainly of leucocytes, alone is virulent (Kolle, see Nicolle and Adil-Bey 1902; Schein 1917, Daubney 1928). Nicolle and Adil-Bey (1902) brought forward evidence to show that the virus, when present in diluted tissue fluids or suspensions, may pass through a Berkefeld N or a Chamberland F candle; the results however are inconstant—possibly because of the intracellular location of the virus. Complement-fixing bodies are present irregularly in the serum of convalescent animals. For laboratory diagnosis reliance is better placed on the

Anaerobic Breakdown of Glucose and Other Hexoses

Fermentation of the Coliform Bacteria.⁴² The coliform bacteria carry out more complex fermentations of glucose than those just described. The details

FERMENTATIONS OF THE COLIFORM BACTERIA

of these fermentations have been elucidated with the aid of cell-free bacterial extracts and isotopic techniques. The accompanying diagram illustrates the manner in which the coliform bacteria, as a group, metabolize pyruvic acid under anaerobic conditions, not all of these reactions occur in any one species. The proportion of fermentation products formed varies with the species, experimental conditions, etc., but a glucose fermentation of *Bact. coli* may be represented by the equation

Acetylmethylcarbinol (acetoin) and related substances are formed only by *Bact. aerogenes*, and this fact is of value in the separation of *Bact. aerogenes* from *Bact. coli*. The enzyme which converts pyruvic acid into acetylmethylcarbinol is a Mg- or Mn-diphosphothiamine-protein complex.⁴³

Butyl Alcohol Fermentations.⁴⁴ Another type of complex bacterial fermentation is carried out by anaerobic organisms such as *Clostridium butylicum*, *Cl. acetobutylicum*, *Cl. welchii* and *Cl. kluyveri*. Pyruvic acid is transformed into acetic acid which condenses with itself to form acetoacetic acid (acetyl phosphate may be an intermediate). Butyric acid and butyl alcohol are then formed by reduction of the acetoacetic acid. In the anaerobic breakdown of glucose by *Cl. butylicum*, fermentation products are formed in approximately the following molar proportions: 50% CO₂, 25% H₂, 12% butyl alcohol, 3% each of isopropyl alcohol, butyric acid and acetic acid, and traces of ethanol.

Attempts have been made to determine whether, independently of aggregation, antibody can retard either the metabolism or the reproduction of bacteria, in a manner similar to the action of the "ablastin" antibody described by Taliaferro for *Trypanosoma lewisi* (see Taliaferro 1948). In the absence of complement, which of course may be bactericidal for bacteria sensitized with antibody, antibody does not decrease oxygen consumption by salmonellae (Sevag and Miller 1948, Harris 1948, Follis *et al.* 1952); with young cultures of *Chr. prodigiosum* and *Sh. flexneri*, indeed, Follis and his colleagues recorded a stimulation of oxygen uptake by specific antibody.

The Availability of Antibody in the Tissues of the Host.

The concentration of antibody in the blood is one of the simplest indications of a state of immunity, and it is possible to determine by experiment the relation between a given blood concentration and a specifically immune state of the animal. This immunity, however, depends on antibacterial qualities not only of the blood, but also on that of the tissues, the intercellular fluids, lymph, and so forth. Moreover, in most natural processes of infection, the defences come into play in the order—tissues, lymphatic system, blood stream, and finally reticulo-endothelial system. Given, then, an animal whose blood contains an adequate concentration of antibody specific for the antigens associated with the virulence of a parasite, we must consider whether the concentration of antibody in other tissues is sufficient for an effective antibacterial response at any of the stages of invasion we have listed. Serum antibodies, whether they result from active or passive immunization, are sooner or later distributed throughout the tissues. They are present in tissue fluids and lymph, but only in very low concentrations in cerebrospinal fluid (see Sohler and Jaulmes 1939).

Thus Pagano (1894), Falloise (1903) and Batelli (1904) found that the concentration of hæmolytin was lower in the thoracic lymph than in the blood serum. Hughes and Carlson (1908), working with normal dogs, horses and cats, found that the concentration of hæmolytin for rabbit corpuscles formed a descending series, in the order—serum, thoracic lymph, neck lymph, pericardial fluid, aqueous humour. Becht and Greer (1910) studied the distribution of normal and immune antibodies in dogs, and in addition the rate of transference of antibodies from the circulating blood to the tissue fluids after passive immunization by the intravenous route. Their findings with regard to the distribution of normal and immune antibodies were in accord with those of Hughes and Carlson. In the actively immunized animals they observed a marked rise in the antibody titre of the serum, thoracic lymph and neck lymph, the relative concentrations in the different fluids maintaining the same order as in the normal animals. After passive immunization, the characteristic distribution of antibodies was established within 4½ hours. These findings were confirmed in all essentials by Hektoen and Carlson (1910).

The thoracic duct, however, receives contributions from all the lymphatic channels of the body, including those from the liver, whose lymph ordinarily contains a high proportion of protein, so that the antibody content of thoracic duct lymph may reflect only the permeability of the liver capillaries to antibody. Thus Freund and Whitney (1929) injected agglutinins intravenously into rabbits and found that antibodies accumulated rapidly in liver lymph, slowly in lymph from the leg. Similarly, Becht and Luckhardt (1916) found that cervical lymph had a lower concentration than thoracic duct lymph of intravenously injected antibody. In rabbits actively immunized with diphtheria toxoid, Takahashi (1936) found 0.67 unit of antitoxin per ml. of blood, and 0.29 unit per ml. of popliteal lymph. Nevertheless, with the exception of locally formed antibody (see Chapter 50) the concentration of antibody in tissue fluids and lymph, like that of other serum proteins, tends to be comparatively low. Thus in rabbits actively immunized with the virus of equine encephalomyelitis, the ratio of antibody titres in blood and brain

THE BUTYL ALCOHOL FERMENTATION

In both of the two complex fermentations described in the preceding paragraphs, pyruvic acid is split to acetic acid, H_2 , and CO_2 by addition of a molecule of water. This reaction is known as the hydroclastic reaction:

However, recent investigations have revealed that the hydroclastic reaction is actually a reversible phosphoryclastic reaction in which acetylphosphate, which contains a high energy phosphate bond, is formed. In *Bact. coli*, the reaction proceeds in two steps:

In *Cl. butylicum*, formic acid is not an intermediate in the formation of H_2 and CO_2 .

Fermentation of Other Sugars, Organic Acids and Alcohols The fermentation of sugars other than hexoses, organic acids and alcohols results in the formation of acids and, sometimes, gases; but, for the most part, the mechanisms involved in these decompositions are unknown. Certain fragmentary ob-

quantities of blood taken from infected animals. Blood, when diluted with saline, and filtered through a Berkefeld or Chamberland candle, still proves infective. By cross-immunity tests in horses and by intracerebral protection tests in mice numerous antigenically different strains of virus can be distinguished (Alexander 1935). The diameter of the virus appears to be about 50 $m\mu$. Prophylactic inoculation may be accomplished by Theiler's method, which consists in the injection of large quantities of immune serum intravenously, together with small quantities of virulent blood subcutaneously, followed by a second serum injection after the appearance of the febrile reaction. More recently, a specially developed neurotropic virus has been used.

INFECTIOUS ANÆMIA OF HORSES

SYNONYM: Swamp Fever.

This disease, which is not to be confused with the swamp fever of human beings caused by *Leptospira grippotyphosa* (see Chapter 82), has a wide geographical distribution, occurring in various parts of Europe, the United States, Canada, Japan, and South Africa. It is most prevalent in low-lying badly drained districts, and reaches its maximum incidence during the summer months. The disease was shown by Vallée and Carré (1904) to be due to a filtrable virus, which is constantly present in the blood stream. By the gradocol membrane technique its size appears to lie between 18 and 50 $m\mu$ (Balozet 1939), and by electronmicrography between 11 and 59 $m\mu$ with an average of 30 $m\mu$ (Reagan *et al.* 1950). Transmission probably occurs by biting flies—*Stomoxys calcitrans*. The disease can be reproduced experimentally by biting insects, but not by contact or feeding; not all workers, however, have been successful with insect transmission (Lemétayer 1949). Equine animals are alone susceptible to the natural disease. Laboratory animals appear to be refractory to experimental inoculation, though it is said that the virus can be established in rabbits by intravenous injection of citrated blood (Reagan *et al.* 1950). The disease may be acute or chronic. The acute form is characterized by fever, extreme weakness, and conjunctival hæmorrhages, the chronic form by general unthriftiness with extreme emaciation. Anæmia does not appear to be a prominent sign. Death may occur in acute cases. Horses may remain carriers for years. There is, as yet, no specific diagnostic test or therapeutic treatment for the disease (for references see Stein 1935).

MALIGNANT CATARRH OF CATTLE

SYNONYM: *Snotsiekte*.

This disease occurs in various parts of the world, and is characterized by fever, catarrh of the oral, nasopharyngeal, and conjunctival membranes, general enlargement of the lymphatic glands, and often symptoms suggesting involvement of the brain or cord. The mortality is subject to considerable variation. Post-mortem examination of fatal cases often reveals petechial hæmorrhages in the stomach, mottling of the liver and kidneys, congestion and petechiæ in the respiratory mucosa, œdema of the lungs, enlargement of the lymphatic glands, and sometimes plate-like extravasations of blood on the surface of the brain. The disease is apparently caused by a virus, which can be transferred to rabbits and back again to cattle (see Daubney and Hudson 1936).

Aerobic Breakdown of Carbohydrate

servations are available, such as those of Kay,⁴⁵ who showed that when mannitol, glucose, glucuronic acid, glycuronic acid and saccharic acid are fermented by *Bact coli*, the yields of the more oxidized products (acetic and succinic acids) rise and those of the reduced products (ethanol) fall as one proceeds from the reduced substrate mannitol to the more highly oxidized saccharic acid. The fermentation of glycerol by this same organism has been found⁴⁶ to yield much the same end products as the fermentation of glucose. Similarly, the fermentation of the four-carbon acids, malic, tartaric and fumaric acids, by *Bact. aerogenes* gives rise to the same products as the glucose fermentation⁴⁷, the fermentation apparently proceeds via oxalacetic acid, which is decarboxylated to pyruvic acid (p. 85).

Energy Yields from Anaerobic Breakdown of Pyruvic Acid. Bacterial fermentation of pyruvic acid always results in the liberation of energy, but the diverse nature of the products of fermentation makes exact calculation of the energy changes very difficult. Under proper conditions (see p. 115), many heterotrophic bacteria, such as *Bact coli*, may grow anaerobically with only pyruvic acid, lactic acid or glycerol as the source of energy. The formation of acetylphosphate and the transfer of its high energy phosphate bond to the adenine nucleotides is of frequent occurrence in the bacterial fermentations and represents one possible mechanism of energy conservation and transfer.

Aerobic Breakdown of Carbohydrate. Comparatively little attention has been paid to the aerobic metabolism of carbohydrate in bacteria, and the details of these processes are not well understood. Certain bacteria are able to oxidize such diverse compounds as methane, benzene, phenol, cholesterol, etc.,⁴⁸ but the substrates for most aerobic bacterial oxidations are the hexoses and their anaerobic fermentation products.

Hexoses may be oxidized without preliminary fermentation. Some bacteria which are unable to ferment glucose can oxidize glucose or glucose-6 phosphate with molecular oxygen.⁴⁹ The acetic acid bacteria are noted for the variety of direct oxidation products which they form. These bacteria can oxidize glucose to gluconic acid, 5 ketogluconic acid, and 2-ketogluconic acid.

Direct Oxidation of Pyruvic Acid. Enzymes which catalyze the oxidation of pyruvic acid to acetic acid and CO_2 are formed by many bacteria. Like the enzymes which decarboxylate pyruvic acid to acetaldehyde and CO_2 or convert it to acetyl methylcarbinol and CO_2 , the pyruvic oxidases are diphosphothiamine protein complexes

susceptible animals are brought together. Sheep are more prone to the disease than goats, and—curiously enough—native sheep are more susceptible than pure-bred animals. The disease is characterized by an incubation period of about 2 days, a sudden rise of temperature to 105–108° F., a fall to normal in 2 days followed by obvious illness, diarrhoea with sometimes blood and mucus in the stools, and—in fatal cases—death within 2–4 days of the onset of obvious symptoms. At post-mortem there is an acute hæmorrhagic gastro-enteritis, the spleen is enlarged, the gall-bladder is distended with bile, and the trachea is congested and may contain blood-stained mucus. The case fatality in native sheep is about 70 per cent. The blood is infective during the fever and for a day after its fall. The infectivity is retained after passage through a Chamberland F candle. Though the urine may also contain the virus, infection does not appear to spread by contact, but is transmitted by the bite of the “brown” tick, *Rhipicephalus appendiculatus*. Ticks can be infected in the nymphal as well as the adult stage, and there is some evidence to suggest that hereditary transmission of the infection may occur. Immunity to the disease persists for, at any rate, some months. No method of artificial immunization has yet proved satisfactory. The “brown” tick is also responsible for carrying East Coast fever in cattle. Dipping cattle at a 3-day interval will help to clear the ground of ticks, and so diminish the risk to sheep of infection with the virus of the Nairobi disease.

EPIZOOTIC ABORTION OF MARES

In addition to infection with *Salm. abortus-equi* or with streptococci, a form of epizootic abortion of mares has been described that appears to be caused by a virus. The disease is very contagious. Abortion occurs, after profuse sweating but no other clinical symptoms, at the 9th to 11th month. There is a slight vaginal discharge of short duration, with rapid and complete recovery of the mare. Dimock and Edwards (1936) observed several outbreaks in the United States. No bacterial cause could be found. In many of the aborted foetuses there was a clear yellow or reddish-yellow exudate in the pleural cavity, numerous small white foci of degeneration in the liver just beneath the capsule, congestion of the mesenteric and colonic lymph nodes, and petechial and lineal hæmorrhages in the heart. Pregnant mares, fed on fluids and tissues from infected foetuses, either before or after Seitz filtration, aborted in 18 to 34 days. Dimock and Edwards obtained doubtful results in their attempted transmission of the disease to guinea-pigs, but Miessner and Harms (1937) in Germany were apparently more successful. By subcutaneous and intraperitoneal inoculation of filtered material from the liver, spleen, kidneys, and stomach contents of aborted foetuses, they reproduced the disease in pregnant guinea-pigs, and carried on infection through 4 passages. The virus was grown in foetal cat lung (Randall *et al* 1954).

FOWL PLAGUE OR FOWL PEST

This is an acute infectious disease of fowls, and exceptionally of geese, which was studied by Landsteiner (1906) and Russ (1906). It does not appear to spread by contact, and the natural mode of infection is unknown. The incubation period is 3–5 days; the symptoms consist of depression and dullness, darkening of the comb and wattles, and inflammation of the buccal mucosa. The disease lasts 2–4 days, and is very frequently fatal (Hutyra and Marek 1926). The experimental disease may be produced in chickens by the inoculation of blood, nasal

THE BUTYL ALCOHOL FERMENTATION

In both of the two complex fermentations described in the preceding paragraphs, pyruvic acid is split to acetic acid, H_2 , and CO_2 by addition of a molecule of water. This reaction is known as the hydroclastic reaction:

However, recent investigations have revealed that the hydroclastic reaction is actually a reversible phosphoryclastic reaction in which acetylphosphate, which contains a high energy phosphate bond, is formed. In *Bact. coli*, the reaction proceeds in two steps.

In *Cl. butylicum*, formic acid is not an intermediate in the formation of H_2 and CO_2 .

Fermentation of Other Sugars, Organic Acids and Alcohols. The fermentation of sugars other than hexoses, organic acids and alcohols results in the formation of acids and, sometimes, gases; but, for the most part, the mechanisms involved in these decompositions are unknown. Certain fragmentary ob-

Electronmicrography shows it to be irregularly globular in shape in the allantoic fluid and sperm-like in saline (Cunha *et al.* 1947, Bang 1948). The virus can be readily cultivated on the chorio-allantoic membrane of the developing chick embryo. It kills the embryo in 21-72 hours; *post mortem*, hæmorrhagic encephalitis and hæmorrhagic lesions, particularly in the developing feather follicles, are striking features (Burnet 1942). Inoculated by the allantoic route, it multiplies abundantly, and the allantoic fluid gives the Hirst agglutination reaction with chicken red blood corpuscles. After intranasal inoculation into mice, it produces consolidation of the lungs. In these and some other ways the Newcastle virus closely resembles the influenza virus of man. It is not, however, pathogenic for ferrets, nor does it appear to be antigenically related to the virus of influenza (Burnet 1942), though it behaves like it in many respects. It is found in the body fluids, organs, and excretions of affected birds. Cross-immunization tests show that the fowl plague and Newcastle viruses are distinct. The disease appears to have been introduced into Great Britain from time to time by infected carcasses from Central Europe.

The degree of infectivity of the Newcastle disease virus for *man* is in question. A few undoubted laboratory infections have occurred, usually characterized by conjunctivitis with mild constitutional symptoms. Nelson and his colleagues (1952) described an outbreak of conjunctivitis among workers engaged in eviscerating and canning poultry; the virus was isolated from the conjunctiva of 4 out of 10 patients examined. Howitt, Bishop, and Kissling (1948) ascribed to this virus a fairly widespread infection resembling influenza or non-paralytic poliomyelitis that occurred year after year in Alabama and Tennessee. The virus itself was not isolated, but neutralizing antibodies were found in the serum of the patients. Evans (1954) found that the serum of some patients convalescent from mumps or from glandular fever neutralized the Newcastle virus, though Newcastle antiserum did not neutralize the mumps virus. On infected farms some workers who had suffered from conjunctivitis contained neutralizing antibodies to the Newcastle virus in their serum to a significant titre.

Diagnosis of the disease in fowls is best made by inoculating the spleen into fertile eggs and testing the allantoic fluid. The disease is inhibited by specific antiserum. In controlling the disease the slaughter policy is recommended where practicable. Some success has been obtained with the use of formalized vaccines, vaccines prepared with crystal violet, and vaccines containing living attenuated virus, but no entirely satisfactory vaccine is yet available (see Doyle and Wright 1950).

INFECTIOUS LARYNGO-TRACHEITIS OF FOWLS

This disease has so far been reported mainly from North America and Australia, though cases have occurred in Great Britain (Asplin 1948). It appears to have been first recognized and studied in the United States by May and Tittsler (1925), Beach (1931), and others. Hyperacute, acute, chronic and asymptomatic forms are recognized clinically (Seddon and Hart 1935). Affected birds suffer from difficulty in respiration. The head is elevated, the neck extended, and air is drawn in through the half-opened beak with a loud wheezing sound. During expiration the head is lowered, and violent fits of coughing may occur, accompanied by the expulsion of masses of clotted blood and mucus. Fowls of all ages are susceptible. The incubation period is 7-12 days. The morbidity in an infected herd is 50-90 per cent. The case fatality varies in different outbreaks from 5-90 per cent.

servations are available, such as those of Kay,⁴⁵ who showed that when mannitol, glucose, glucuronic acid, glycuronic acid and saccharic acid are fermented by *Bact. coli*, the yields of the more oxidized products (acetic and succinic acids) rise and those of the reduced products (ethanol) fall as one proceeds from the reduced substrate mannitol to the more highly oxidized saccharic acid. The fermentation of glycerol by this same organism has been found⁴⁶ to yield much the same end products as the fermentation of glucose. Similarly, the fermentation of the four-carbon acids, malic, tartaric and fumaric acids, by *Bact. aerogenes* gives rise to the same products as the glucose fermentation⁴⁷; the fermentation apparently proceeds via oxalacetic acid, which is decarboxylated to pyruvic acid (p 85).

Energy Yields from Anaerobic Breakdown of Pyruvic Acid Bacterial fermentation of pyruvic acid always results in the liberation of energy, but the diverse nature of the products of fermentation makes exact calculation of the energy changes very difficult. Under proper conditions (see p. 115), many heterotrophic bacteria, such as *Bact. coli*, may grow anaerobically with only pyruvic acid, lactic acid or glycerol as the source of energy. The formation of acetylphosphate and the transfer of its high energy phosphate bond to the adenine nucleotides is of frequent occurrence in the bacterial fermentations and represents one possible mechanism of energy conservation and transfer.

Aerobic Breakdown of Carbohydrate. Comparatively little attention has been paid to the aerobic metabolism of carbohydrate in bacteria, and the details of these processes are not well understood. Certain bacteria are able to oxidize such diverse compounds as methane, benzene, phenol, cholesterol, etc.,⁴⁸ but the substrates for most aerobic bacterial oxidations are the hexoses and their anaerobic fermentation products.

Hexoses may be oxidized without preliminary fermentation. Some bacteria which are unable to ferment glucose can oxidize glucose or glucose-6-phosphate with molecular oxygen.⁴⁹ The acetic acid bacteria are noted for the variety of direct oxidation products which they form. These bacteria can oxidize glucose to gluconic acid, 5 ketogluconic acid, and 2 ketogluconic acid.

Direct Oxidation of Pyruvic Acid Enzymes which catalyze the oxidation of pyruvic acid to acetic acid and CO_2 are formed by many bacteria. Like the enzymes which decarboxylate pyruvic acid to acetaldehyde and CO_2 or convert it to acetylmethylcarbinol and CO_2 , the pyruvic oxidases are diphosphothiamine-protein complexes

egg passage, but a satisfactory vaccine is still awaited. The common method of protection is to infect the chicks with virulent material before egg production begins (Beaudette 1949).

BLUE COMB OF CHICKENS

SYNONYMS: Pullet disease, X Disease.

This disease has been observed in the north Atlantic and north central areas of the United States and on the Pacific coast. It affects pullets mainly 5-7 months of age, though chicks only 4 weeks old may be attacked. Turkeys may also suffer. The incidence is highest in the summer months. The morbidity and mortality in a flock are very variable. According to Jungherr and Levine (1941), who described the disease, the morbidity varies from 0.1 to 100 per cent. with a mean of about 20 per cent., and the case fatality from 0.2 to 53 per cent. with a mean of about 5 per cent. The disease is characterized by a fall in egg production and food consumption, darkening of the comb, droopiness, cyanosis, dehydration, diarrhoea or constipation, and occasionally pyrexia. Pathologically, the chief lesions are focal necrosis of the liver, serous petechiæ, enlargement of the pancreatic islands, patchy muscular degeneration, and nephrotic changes in the renal glomeruli and tubules. Jungherr and Levine regarded the disease as an endogenous toxæmia, but Waller (1942, 1944) brought evidence in favour of a virus origin. From the blood and liver of acutely affected birds he isolated a filtrable agent that grew readily on the chorio-allantoic membrane of the developing chick embryo. Susceptible chickens inoculated with infected membrane become depressed and cyanotic in 3-4 days. They do not die but, if killed after 4-5 days, they show subcutaneous œdema, generalized jaundice, hæmorrhages into the skeletal muscles, petechial hæmorrhages in other organs, congestion and swelling of the liver and kidneys, and acute catarrhal hæmorrhagic duodenitis. Fæces of experimentally infected birds are infective to other birds by the mouth. Intraperitoneal inoculation of susceptible chickens with a bacteria-free filtrate of infected fæces likewise reproduces the disease. The virus passes through a Chamberland L3 and a Sertz filter. Its relationship to the disease must await further inquiry. There is evidence that a vaccine prepared from the dried chorio-allantoic membrane of infected chick embryos may afford some protection (Waller 1944).

MISCELLANEOUS DISEASES OF FOWLS AND OTHER BIRDS

Eveleth, Bohn and Goldsby (see Bohn *et al.* 1949) described a disease of poults and baby chicks in North Dakota attended by a high mortality during the first 3 weeks of life. The outstanding lesion was necrosis of the abdominal wall around the navel. Bohn and his colleagues (1949) isolated a virus from poults dead of the disease and carried it by serial transfer through chick embryos. The disease was reproduced in chicks by feeding and by swabbing the navel with the amniotic fluid of dead embryos. The virus is more pathogenic for turkeys than for chicks.

Levine and Fabricant (1950) described a highly fatal disease of young ducklings on Long Island in 1948. The principal findings at necropsy were an enlarged hæmorrhagic liver and swollen injected kidneys. A virus was isolated by inoculation into the allantoic cavity of 9-day-old chick embryos. It differed from the virus of Newcastle disease in its failure to agglutinate fowl red blood corpuscles, to kill embryos consistently within 48 hours, or to be neutralized by Newcastle antiserum. Virus from infected eggs repro-

The exact function of diphosphothiamine, or cocarboxylase, in the metabolism of pyruvic acid is not known, and the reversible oxidation-reduction of this coenzyme has not been demonstrated.

In *Bact. coli*⁵⁰ and the gonococcus,⁵¹ pyruvic acid is oxidized in a reaction in which diphosphothiamine, but not inorganic phosphate, is required, and electron transport involves the flavoproteins and the cytochrome system. In *Proteus vulgaris*⁵² the oxidation of pyruvic acid also proceeds without uptake of phosphate, but the pyruvic oxidase of this bacterium is a Mg-diphosphothiamine protein which apparently reacts directly with oxygen. In these types of pyruvic acid oxidation, the equation for the reaction is:

Lipmann⁵³ has described a third type of pyruvic acid oxidation in *Lactobacillus delbrueckii* in which the oxidation is coupled with the uptake of inorganic phosphate and acetylphosphate is formed.

The pyruvic oxidase of *L. delbrueckii* is a Mg-diphosphothiamine protein, and oxygen uptake is due to the presence of an autooxidizable protein (p. 71).

Anaerobic breakdown products of pyruvic acid are also oxidized by molecular oxygen. Ethanol is oxidized to acetic acid by the bacteria responsible for the vinegar "fermentation"; the propionic acid bacteria oxidize acetaldehyde to acetic acid, and acetic acid itself may be oxidized to CO_2 and H_2O .

Oxidation of the Four-Carbon Dicarboxylic Acids. Many bacteria rapidly oxidize the four-carbon dicarboxylic acids. Anaerobically, the reverse reactions occur, and oxalacetic acid may be reduced to succinic acid.

Szent-Gyorgyi and Krebs have shown that the oxidation of carbohydrates in higher animals is catalyzed by the four-carbon dicarboxylic acids, and such catalysts also occurs in bacteria. For example, in the oxidation of glucose by *Micrococcus lysodeikticus*, small amounts of fumaric acid cause an increased

oxygen uptake five times greater than the amount of oxygen required for the complete oxidation of the added fumaric acid to CO_2 and H_2O .⁵⁴

*The Szent-Gyorgyi Cycle.*⁵⁵ According to Szent-Gyorgyi such catalysis occurs because fumaric and oxalacetic acids act as hydrogen acceptors in the oxidation of glucose and are reduced to succinic acid which is reoxidized by molecular oxygen. This series of reactions is referred to as the Szent-Gyorgyi cycle. Many bacteria aerobically oxidize succinic acid faster than glucose itself, and the rate of anaerobic glucose oxidation in the presence of excess fumaric acid may be as great as the rate of aerobic glucose oxidation. Thus, it is possible for the Szent-Gyorgyi cycle to function in the respiration of some bacteria, but its actual occurrence has not been observed.

*The Krebs Cycle.*⁵⁵ A considerable portion of the carbohydrate metabolized by most aerobic organisms is oxidized completely to CO_2 and H_2O , usually by way of pyruvic acid as an intermediate. In a wide variety of organisms, the complete oxidation of pyruvic acid is brought about, not by a single reaction, but by a cyclic series of reactions, the tricarboxylic acid cycle of Krebs. In this scheme, pyruvic acid condenses with oxalacetic acid to form a six-carbon tricarboxylic acid which is oxidized and decarboxylated in a series of reactions ending in the regeneration of oxalacetic acid. The net reaction of the cycle is:

The tricarboxylic acid cycle has been demonstrated in mammalian and avian tissues and in protozoa. It probably also functions in plants and fungi. While almost all of the reactions of the tricarboxylic acid cycle occur in bacteria, it has not been shown that the cycle functions in the oxidation of pyruvic acid by bacteria. The chief difficulty in demonstrating the Krebs cycle in bacteria lies in the inability of most bacteria, *Bact. coli* for example, to oxidize citric, isocitric or *cis*-aconitic acid. Those bacteria which can oxidize the tricarboxylic acids (*Bact. aerogenes*, etc.) apparently form only succinic acid, acetic acid and CO_2 , not α -ketoglutaric acid as required by the tricarboxylic acid cycle. However, Werkman⁵⁴ believes that some sort of a tricarboxylic acid cycle may be operative in bacteria.

Energy Yield from Aerobic Oxidation of Carbohydrates. The yield of useful energy from complete aerobic oxidation of glucose to CO_2 and H_2O is much greater than the yield from anaerobic conversion of glucose to lactic acid, ethanol, etc.

In the tissues of higher animals, glucose and other carbohydrates are oxidized

⁵⁴ Werkman in *A Symposium on Respiratory Enzymes*, University of Wisconsin Press, Madison, 1942, p. 258.

⁵⁵ For evaluation of the role of the Szent Gyorgyi cycle and the tricarboxylic acid cycle in bacterial metabolism, see Krebs *Advances in Enzymology*, 1943, 3 191, and reference 54.

Synthesis of Cell Substances from Carbohydrates

almost completely to CO_2 and H_2O under aerobic conditions. In these tissues, the energy liberated in the oxidation of carbohydrate is conserved with great efficiency in high energy phosphate bonds. As many as fifteen such bonds may be generated by the oxidation of a single mole of pyruvic acid.⁷⁶ This represents about the same energetic efficiency as obtained in the anaerobic oxidation of glucose. When bacteria oxidize carbohydrate completely to CO_2 and H_2O , it is probable that a similar formation of high energy phosphate bonds occurs, but it has not yet been experimentally demonstrated. When aerobic oxidation of carbohydrate is incomplete, as in many bacterial oxidations, the energy change is not nearly so great. For instance, the utilizable energy released in the oxidation of pyruvic acid to acetic acid and CO_2 is only sufficient to generate one energy-rich phosphate bond.

Synthesis of Cell Substances from Carbohydrates. The breakdown of carbohydrates by the series of energy-yielding reactions just discussed is actually only one of several ways in which carbohydrates are utilized by the bacterial cell. They may also be combined with CO_2 to form new substances, converted into oligosaccharides and polysaccharides, or transformed into non-carbohydrate cell substances. These are the processes by which bacteria change the carbohydrates of the culture medium into their own highly specific cellular components. Such reactions generally do not proceed spontaneously because they require an external source of energy. The energy-requiring actions may be designated as synthetic reactions in contrast to the energy-yielding degradative reactions. In the living cell, the two types of reactions occur in such a manner that the energy released in the breakdown of carbohydrates is used in part for the synthesis of other carbohydrates, usually in the form of high energy phosphate bonds.

Assimilation of Carbon Dioxide.⁷⁷ It has been known for many years that CO_2 is involved in the metabolism of heterotrophic bacteria, because it had been repeatedly observed that many bacteria did not grow when all CO_2 was removed from the culture medium with CO_2 -free air. However, proper interpretation of these findings did not come until 1935, when Wood and Werkman discovered that the heterotrophic propionic acid bacteria fix carbon dioxide into organic linkage, mainly in the carboxyl groups of the four-carbon dicarboxylic acids. Later investigations employing isotopically labelled CO_2 confirmed this original observation and demonstrated the occurrence of CO_2 fixation in other bacteria, yeasts, fungi, protozoa and higher animals.

Several different primary fixation reactions are responsible for the assimilation of CO_2 in heterotrophic bacteria. They may be classified on the basis of the substance which reacts with CO_2 (the specified organism is that in which the reaction was first reported):

⁷⁷ This subject has been reviewed by Werkman and Wood. Advances in Enzymology, 1942, 2 135, Krebs Ann. Rev. Biochem., 1943, 12 529, and Wood Physiol. Rev., 1946, 26 198.

CHAPTER 89

FILTRABLE VIRUS DISEASES—*Continued*

E. GROUP CHARACTERIZED BY TUMOUR FORMATION

THE group of virus diseases characterized by tumour formation is of particular interest in affording a possible clue to the genesis of neoplasms. In this chapter we must confine ourselves to factual description; but those who are interested in the wider aspects of the subject would do well to refer to the far-reaching speculations of Andrewes (1939*b*, 1950), of Rous (1943), and of Gye (1949). It should be pointed out that there is no sharp line of demarcation between viruses producing tumours and other viruses. Some viruses cause proliferation of the cells they attack, others necrosis and destruction. Some, such as that of rabbit fibroma, have variants, one causing proliferation, the other necrosis and inflammation (Andrewes 1951). Nevertheless there are groups of viruses having strong tendencies to cause proliferation, and with these we shall deal here.

FOWL LEUCÆMIA

This is an infectious disease of the blood-forming organs, associated with atrophy of the bone marrow and changes in the viscera. The disease may be transmitted to normal fowls, but not to other birds, by intravenous inoculation with the citrated blood of infected fowls. According to Ellermann (1921), the virus can pass through a Berkefeld candle. By electronmicrography it appears to be about 120 $m\mu$ in diameter (Sharp *et al.* 1952). Ellermann found that one strain of virus gave rise to three different types of leucæmia: (1) a myeloid type; (2) a lymphatic type; (3) an intravascular lymphoid type, characterized by intravascular deposits of lymphoid cells. An increase of virulence was noted during its passage through fowls, shown by a shortening of the interval between inoculation and death, from 15 to 20 weeks at the commencement, to 6 to 8 weeks at the end of the series of experiments. In spite, however, of the increased rate of killing, the infecting power of the virus, as judged by the proportion of successful inoculations, remained approximately constant at 20–40 per cent. Ellermann was unable to produce active immunity to the disease by subcutaneous inoculation of virulent material.

Furth (1932) found that infection could be transmitted by 0.000,001 ml. of cell-free plasma, and that the virus could withstand drying for at least 54 days. He also (1933) described a new transmissible strain of chicken leucosis which gave rise to (1) lymphomatosis with or without tumour formation, (2) myelocytomatosis with or without leucæmia, (3) endothelioma. The histology of the disease is beautifully illustrated in the monograph by Andersen and Bang (1928).

 a. in *Cl. butylicum*
 $\text{CH}_3\text{COPO}_3\text{H}_2 + \text{H}_2 + \text{CO}_2 \rightleftharpoons \text{CH}_3\text{COCOOH} + \text{H}_2\text{PO}_4$
 b. in *Bact. coli*
 $\text{H}_2 + \text{CO}_2 \rightleftharpoons \text{HCOOH}$
 $\text{HCOOH} + \text{CH}_3\text{COPO}_3\text{H}_2 \rightleftharpoons \text{CH}_3\text{COCOOH} + \text{H}_2\text{PO}_4$
- (4) C_2 - C_1 addition
 in *Propionibacterium pentosaceum*

$$\begin{array}{ccc} \text{COOH} & & \text{COOH} \\ | & & | \\ \text{C=O} + \text{CO}_2 & \rightleftharpoons & \text{C=O} \\ | & & | \\ \text{CH}_3 & & \text{CH}_2 \\ & & | \\ & & \text{COOH} \end{array}$$

Of these modes of addition, the carboxylation of pyruvic acid to oxalacetic acid, the Wood-Werkman reaction, is the most widely distributed. An additional primary fixation reaction, the addition of CO_2 to α -ketoglutaric acid to form oxalosuccinic acid, occurs in animal tissues but has not yet been found in bacteria.⁵⁴ Reductive fixation of CO_2 (fixation reactions 1 and 2) is accompanied by the oxidation of a hydrogen donor, which may be any of several simple organic compounds, such as ethanol. In non-reductive fixation (fixation reactions 3 and 4) the CO_2 appears in the carboxyl group of an organic acid without being reduced. After CO_2 has been incorporated into an organic compound by one of the primary fixation reactions, further metabolic reactions may lead to the distribution of the fixed CO_2 among many different substances. Thus, Wood and Werkman found that the CO_2 fixed in oxalacetic acid by the propionic acid bacteria also appeared in the other four-carbon dicarboxylic acids and in propionic acid.

The ability to fix CO_2 into organic linkage was once thought to be the exclusive property of autotrophic organisms, but after demonstration of CO_2 fixation in the heterotrophic propionic acid bacteria, the line between autotrophes and heterotrophes was redrawn by assuming that only autotrophes can join two molecules of CO_2 together in organic linkage. However, when it was found that *Cl. acidurici* can synthesize acetic acid from two molecules of CO_2 , even this difference between the two metabolic types was destroyed. The distinction between autotrophic and heterotrophic CO_2 fixation seems to be only quantitative: heterotrophes derive only a fraction of their carbon compounds from CO_2 , while autotrophes obtain all of their compounds by assimilation of CO_2 .

Studies of the energetics of CO_2 assimilation have emphasized the close similarity of autotrophic and heterotrophic mechanisms. Incorporation of CO_2 into an organic compound requires the expenditure of energy. In the autotrophe, *Thiobacillus thiooxidans*, CO_2 is fixed with energy gained from the oxidation of sulfur to sulfate, and ATP takes part in the transfer of energy from the sulfur-oxidizing to the CO_2 -fixing system (p. 81). In a comparable

⁵⁵ Ochoa. Jour. Biol. Chem., 1948, 174 133.

KCl, and a fragment of chick embryo have been added. He believed that the tumour-forming activity of this virus is dependent on the presence of another, non-living factor, which determines the type of cell which is infected, and hence the type of tumour which is produced. This second, auxiliary agent he called the "specific factor." The evidence in favour of the dual nature of the active agent in tumour filtrates consists in the differential action of aerobic incubation and of various chemical agents. In an extensive series of experiments Gye found that (a) primary "cultures" incubated aerobically at 37° C. for 3 days were inactive; (b) filtrates, obtained by passing the ground-up tumour through a mixture of paper pulp and sand, when treated with chloroform, were inactive; but that (c) the inactivated "cultures" and the chloroform-inactivated filtrates, when acting in combination, gave rise to typical tumours. He would regard the specific factor in the "cultures" as being destroyed by aerobic incubation, and the virus in the tumour filtrate as being destroyed by the chloroform. He would also extend the conclusions based on these results to malignant neoplasms in general. Gye's conclusions have never been satisfactorily confirmed, though they have stimulated considerable interest in the virus causation of cancer (see also Gye and Mueller 1929, Amies and Carr 1939). According to Epstein (1951) repeated freezing and thawing destroys the Rous sarcoma cells but not the virus itself. Similar experiments to study the effect of freezing, drying and thawing on tumours of different types with a view to separating a possible virus from the cells in which it is contained are in progress (see Craigie 1949). The observations of Duran-Reynals (1942) that the Rous virus, when adapted to ducklings, produces a tumour with a different histological pattern, have likewise aroused interest by indicating the existence of a plasticity in the virus that would not otherwise have been suspected.

Besides the Rous sarcoma, other filtrable tumours of fowls are known. McIntosh (1933) and McIntosh and Selbie (1939) reported that tumours induced by tar may be transmitted to normal birds by cell-free filtrates; and Selbie and McIntosh (1939) found that the filtrability of fowl tumours may be increased by such procedures as proteolytic digestion or freezing and thawing, which presumably act by liberation of virus from the cells in which it is growing. The demonstration by Ledingham and Gye (1935) of what appear to be elementary bodies in infective filtrates, and the immunological studies of Andrewes (1931, 1932, 1933, 1936b, 1939a), suggest more and more strongly that viruses, not differing in any important respect from those known to give rise to ordinary infectious diseases, play an essential part in the causation of these tumours (see Andrewes 1934). The particle size of the Rous sarcoma virus was determined by Elford and Andrewes (1935, 1936). By the gradocol membrane technique it appears to be 75-150 m μ in diameter, and by the centrifugation method 60-70 m μ .

MOLLUSCUM CONTAGIOSUM

This is a contagious skin disease of man characterized by the formation of small red masses, which later take on a warty appearance, undergo necrosis, and discharge caseous material. MacCallum (1892) described peculiar bodies in material taken from the disease, which he regarded as due to nucleolar extrusion. They were later described by Lipschütz (1907) as very small rounded bodies, about 0.25 μ in diameter, arranged singly or less often in pairs. They occur in the epidermal cells, are intracytoplasmic, and stain a brilliant red with eosin or phloxine. These molluscum bodies were at one time considered to be parasites, but are now generally

Synthesis of Cell Substances from Carbohydrates

in fashion, energy for the reductive fixation of CO_2 by *Methanobacterium omelianskii* and *Cl. acidurici* is obtained from the simultaneous oxidation of organic substrates. In the carboxylation of acetylphosphate to pyruvic acid in *Bact. coli* and *Cl. butylicum*, the high energy phosphate bond of acetylphosphate is probably the source of energy used in fixation, since pyruvic acid is not formed when acetylphosphate is replaced by acetic acid. Carboxylation of pyruvic acid to oxalacetic acid in the Wood-Werkman reaction is catalyzed by the enzyme oxalacetate carboxylase, which has been found both in bacteria and in animal tissues.

The energy change in the reaction is such that the equilibrium of the reaction is far to the left in favor of decarboxylation of oxalacetic acid. However, when ATP is added to pyruvic acid and CO_2 in the presence of Mn^{++} and oxalacetate carboxylase, oxalacetic acid is formed in amounts detectable by isotopic tracer techniques. The function of ATP in this reaction is unknown.

Assimilation of CO_2 in autotrophs is the source of all organic compounds synthesized by these organisms, but in heterotrophs the function of CO_2 fixation is not so clear. However, from the relatively few direct products of CO_2 fixation, an almost unlimited number of compounds may be produced in further metabolic reactions, and it has been suggested that CO_2 fixation functions in the synthesis of essential metabolites, notably the four-carbon dicarboxylic acids and certain amino acids.

Synthesis of Oligosaccharides and Polysaccharides. The formation of the glycosidic bond is the essential reaction in these syntheses.

Since the glycosidic bond has a higher energy content than the products of its hydrolysis, the equilibrium of the reaction is in favor of hydrolysis. Therefore, an external source of energy must be used to drive the reaction in the direction of synthesis of the glycosidic bond. There are at least two mechanisms for this.

round or rod-shaped bodies (see also Lipschütz 1927). The pathogenesis of the disease is described by Fenner and Woodroffe (1953).

The virus is widely distributed throughout the tissues, though most abundant in the swollen tissues and lymph glands. It is killed by heat at 50° C. in 15 minutes. It is quickly inactivated by a pH of less than 4.6. It withstands the action of glycerol for a year in the ice-chest. It is highly species-specific, and appears to be almost uniformly fatal for the domestic rabbit (see Rivers 1930, Findlay 1933, Hyde and Gardner 1933, Ledingham 1937). Elementary body suspensions were prepared by Rivers and Ward (1937). They were shown to contain a soluble antigen, which could be demonstrated as a precipitinogen in the serum of infected animals. This antigen, which is a heat-labile protein, stimulates the production in rabbits of precipitins and agglutinins, but not of neutralizing antibodies (Rivers *et al.* 1939). By microscopical examination van Rooyen (1937*b*) estimated the elementary bodies to be about 0.31–0.36 μ in diameter, but other methods suggest a size of only 125–225 $m\mu$ (see Mueller 1941, Stanley 1943). Electronmicrographs reveal elementary bodies, mainly 100–400 $m\mu$ in diameter, within the stellate cells, though smaller particles about 30–45 $m\mu$ across may also be seen (Epstein *et al.* 1952). The virus can be cultivated on the chorio-allantoic membrane of the developing chick embryo (Lush 1937, Hoffstadt *et al.* 1941). There are reasons for regarding the virus as belonging to the pox group. Both vaccinia and myxoma viruses have the same brick-shaped appearance with dense pepsin-resistant central bodies, and both are of the same size (Farrant and Fenner 1953).

Aragão (1942, 1943) first showed that the reservoir of myxomatosis in Brazil was the native rabbit, and that infection was transmitted by mosquitoes. The disease was introduced into Australia in 1950 in the hope of exterminating the enormous population of wild rabbits. After a long latent period it flared up and caused a most destructive epizootic. In the summer spread occurred mainly along rivers and on flooded lands where mosquitoes breed (Ratcliffe *et al.* 1952). According to Araújo (1942, 1943) the mosquito acts purely as a mechanical carrier. After insertion into infected epithelial cells, the proboscis may remain infective for 17 days or even longer (see Fenner and Woodroffe 1952). The disease was introduced into France in 1952 and rapidly spread over the whole country and on to other parts of Europe including Great Britain. Transmission of infection over long distances and during the winter as well as the summer months indicated that the mosquito alone was not responsible; it is thought that birds (Ramon 1953) and rabbit fleas (*Spilopsyllus cuniculi*) may have played a part (Andrewes 1954). Whether the disease will prove to be of lasting value for combating the rabbit, or whether the rabbit will develop a resistance towards it as the Bombay rats have done towards plague, the future alone will tell.

The relation of this virus to the virus of infectious fibromatosis of rabbits will be discussed below. A neurotropic strain of the myxoma virus was developed by Hurst (1937) as the result of serial passage through the brain of rabbits. This strain did not prove fatal on intracutaneous inoculation, and the histological picture to which it gave rise differed from that of the parent strain. Animals inoculated with the neuromyxoma strain were protected against subsequent inoculation with the myxoma-producing virus. Vaccination, however, in practice is generally carried out with a strain of the fibroma virus, and is used particularly for the protection of hutch rabbits in countries where the disease is endemic. Though the fibroma virus protects against the clinical manifestations of myxomatosis, it apparently does

nisms for synthesis of polysaccharides and oligosaccharides, both of which meet the energy requirement with the high energy phosphate bonds of ATP.

If the semi-acetal hydroxyl is converted into a phosphate ester, glucose-1-phosphate, the glycosidic bond is easily formed because the phosphate ester bond has about the same energy content as the glycosidic bond itself. Thus, sucrose may be formed in *Pseudomonas saccharophila* and *Leuconostoc mesenteroides* by the reaction.³⁰:

Cori³⁹ has carried out the *in vitro* synthesis of starch and glycogen by similar reactions catalyzed by phosphorylases from plant and animal sources.

A small amount of preformed polysaccharide is necessary for this reaction, because phosphorylase acts to add new glucose units to existing terminal units in the polysaccharide. Although synthesis of polysaccharides by this method has not been observed in bacteria, it is likely that it does occur.

New glycosidic bonds may also be formed at the expense of existing glycosidic linkages. Such reactions occur with little energy change and are thus reversible. The polymeric degradation of sucrose to form levans and dextrans has already been described. This mode of synthesis is widely distributed in bacteria. Dextran, a polymer of glucose units joined in 1,6-glycosidic linkages, is found in *Leuconostoc mesenteroides* and in some types of pneumococcus. Levans are polymeric 2,6-glycosides of fructose, and levans of close chemical and immunological similarity are present in several species of *Bacillus*, one of *Aerobacter*, and two of *Streptococcus*.³¹

The manner in which the energy for all these syntheses is eventually derived from ATP may be illustrated in a diagram adapted from Avineri-Shapiro and Hestrin⁶⁰:

Oxidative Assimilation.⁶¹ In a culture of growing bacteria it is obvious that the constituents of the medium are being converted into bacterial cell material. However, it was not fully realized before the work of Barker and Giesberger that even resting, non-proliferating cells do not oxidize their carbohydrate substrates completely to CO_2 and H_2O but instead assimilate a large portion of

³⁰ Cori, Swanson, and Cori. *Fed. Proc.*, 1945, 4 234.

⁶¹ Clifton. *Advances in Enzymology*, 1946, 6:269.

moments after injection. Proceeding on this assumption, they attempted to measure the distribution of antibody between blood and tissue by comparing the concentration of antitoxin which neutralizes toxin on direct injection of the two into the tissue, with the blood concentration required to protect the tissue against an injection of toxin alone (indirect neutralization). In guinea-pigs the ratio of the two concentrations of antitoxin was about 20 for diphtheria and staphylococcal toxins given intradermally; in guinea-pigs and rabbits it varied between 50 and 1 for different batches of tetanus toxin given intracerebrally (Friedemann *et al.* 1939, Friedemann and Zuger 1939*b*; see also Friedemann *et al.* 1944, 1946*a, b*). Other workers have found no evidence of a rapidly established distribution. Andersen (1937), for example, observed that the antibody content of the skin of rabbits passively immunized against vaccinia by the intravenous route was relatively low after one day, and was equal to that of the blood after 7 days. Miles (1949), however, demonstrated that "indirect" neutralization of intradermal diphtheria toxin by circulating antitoxin was not immediate, but progressive, depending presumably on the rate of passage of antibody through the capillary endothelium; and that toxin was fixed to the tissues at a relatively slow rate. He concluded that, since the indirect neutralizing dose was in part determined by these two processes, its ratio to the direct neutralizing dose was not a valid measure of the intra- and extra-vascular concentrations of antibody.

Friedemann's ratios, though they are not measures of the distribution of antibody between blood and tissues in the uninfected animal, are nevertheless indications of the magnitude of the antibody levels required in the blood of passively immunized animals for a protective effect in the tissues, irrespective of whether that protection is afforded by antitoxin already in the tissues, or by antitoxin passing from the blood to the tissues. When we consider the greater complexity of factors concerned in the action of tissue cells and fluids on bacteria, it will be clear that the blood levels necessary for the suppression of a tissue infection may be much higher (see also Fox 1943, Schlesinger, Olitsky and Morgan 1944).

The Availability of Antibody at Mucous Surfaces.

Antibody is demonstrable in the contents of the alimentary canal ("copro-antibody"), in the urine, and in the uterine cavity. Although certain serum globulins have been shown to pass from the circulation to the lumen of the gut, antibodies in the circulation by no means always appear in the faeces. Cholera antibody in the guinea-pig, for example (see Burrows *et al.* 1947, Burrows and Havens 1948, Koshland and Burrows 1950), appears to be formed locally in response to a local antigenic stimulus, and is moreover protective. Local formation appears also to be responsible for the presence of dysentery copro-agglutinins in man and rodents (González and Koppisch 1951), and of antibodies to *Trichomonas fetus* in the uterine cavity of the cow (Kerr and Robertson 1947; see also Pierce 1947, 1953). Naylor and Caldwell (1953) distinguish the local formation of salmonella agglutinins in the human bladder, as a sequel to infection, from the appearance of circulating antibodies in the urine, as the result of unrelated pathological changes in the bladder wall leading to exudation of serum proteins. In experimental *V. cholerae* gastro-enteritis of guinea pigs, which is mainly a superficial infection of the alimentary mucous membranes, Burrows and Ware (1953) demonstrated free antibody in the lumen of the gut of parenterally immunized animals associated with an immunity to oral infection with the vibrio. They also passively immunized guinea-pigs by antibody given orally.

The observation of MacLeod and his colleagues (1945) that immunization of soldiers with certain type-specific pneumococcal polysaccharides significantly diminished the carrier rate for the corresponding pneumococcal types, but left unaffected the carrier rate for unrelated types, is also consistent with the view that antibody

Regulation of Carbohydrate Metabolism

the carbohydrate into cell substance. In the colorless alga, *Prototheca zopfii*, the first organism studied by Barker, 50 to 80 per cent of simple substrates such as acetic acid and ethanol were assimilated into cell substances with the empirical formula of carbohydrate. This phenomenon, called by Barker oxidative assimilation, is of general occurrence in microorganisms and has been observed in several species of bacteria, yeasts and algae. In several experiments, the assimilated material has actually been identified as carbohydrate. Low concentrations of certain cell poisons, sodium azide and 2,4-dinitrophenol in particular, may inhibit the oxidative assimilation of a substrate and allow its complete oxidation to take place, apparently without inhibiting other metabolic processes. It is of interest that both these poisons interfere with the formation of energy-rich phosphate bonds.⁶² However, there is as yet no direct evidence that energy-rich phosphate bonds are involved in oxidative assimilation. Clifton has suggested that oxidative assimilation is brought about, not by energetic coupling of synthetic and degradative reactions, but by oxidative degradation of carbohydrate to simple "building blocks" such as acetaldehyde which may be converted into carbohydrate through a series of reactions not requiring energy from an independent system.

Formation of Amino Acids from Carbohydrates. The carbon skeleton of metabolized carbohydrate may be converted into amino acids, purines, pyrimidines, fatty acids, etc. The ability of heterotrophic bacteria to carry out these transformations is well illustrated by the growth of organisms such as *Bact. coli* in a medium containing glucose as the sole organic compound. Although other carbohydrates and carbohydrate derivatives undoubtedly form amino acids, the four-carbon dicarboxylic acids appear to be especially active in amino acid formation. Oxalacetic and α -ketoglutaric acids may be reductively aminated to aspartic and glutamic acids in bacteria (p. 109), and the formation of glutamic acid has been studied in detail.

Amino acids may also be formed from carbohydrate in transamination reactions

Regulation of Carbohydrate Metabolism. Higher organisms possess complex regulatory mechanisms which determine the pathways and control the rate of carbohydrate metabolism. These mechanisms are largely hormonal in nature. Bacteria possess no such formidable regulatory mechanisms, but even in bacteria the metabolism of carbohydrate is governed by the environment in which the cells are suspended. The temperature, the pH of the medium, the concentration of available substrate, and the presence or absence of oxygen may affect the rate of metabolism and the nature of the end products produced. A classical example of such a controlling factor is the effect of molecular oxygen upon the metabolism of organisms with both aerobic and anaerobic

⁶² For literature citations, see Lardy and Elvehjem, *Ann. Rev. Biochem.*, 1945, 14-16.

has been adapted to serial passage through the domestic rabbit loses this property after a single passage through the cotton-tail rabbit (Selbie *et al.* 1948). The interesting observation was made by Syverton and Berry (1947) that papilloma cells could be infected with certain other viruses, such as B virus, myxoma virus and vaccinia virus. The papilloma virus can infect epidermal tumours induced by tar, and may bring about in them an abrupt change into carcinomata; direct demonstration of the virus in the carcinomatous tumour has so far failed, but its presence can be shown by serological methods (Rous 1943). An even more rapid method of bringing about the carcinomatous state is to apply methylcholanthrene and tar to virus-induced papillomata; the chemical agents appear to act, not as ordinary stimulants of cell proliferation, but as specific carcinogens affecting the virus (Rous and Friedewald 1944).

The papilloma virus is filtrable through a Berkefeld candle, resists the action of glycerol, and is killed by exposure to 70° C. but not 67° C. for 30 minutes. By the gradocol membrane technique its size has been computed as 23-35 $m\mu$, and by the centrifugation technique as 32-50 $m\mu$ (Schlesinger and Andrewes 1937). Studies by the electron microscope suggest that the particles are spherical and have a mean diameter of about 44 $m\mu$ (Sharp *et al.* 1942). Rabbits with experimentally produced papillomata are partly or completely immune to re-infection, and their serum has neutralizing and complement-fixing properties (see Kidd 1938). Artificial immunization by intraperitoneal injection of glycerolated or non-infective virus has been described (Shope 1937).

ORAL PAPILLOMATOSIS OF RABBITS

Parsons and Kidd (1913) met with a disease among domestic rabbits in New York characterized by the occurrence of small, usually multiple, benign papillomata on the under side of the tongue. They persist often for several months but, unlike the Shope papilloma, do not become malignant. The disease can be reproduced in rabbits and horses, but not in other animals, by local inoculation of a tumour suspension. The resulting lesions are strictly confined to the oral mucosa—a site which is not affected by the Shope virus. Infection does not spread readily by contact. It is probably transferred from the mother to the young by suckling, and remains latent till it is activated by trauma or, experimentally, by tar. The virus passes through a Berkefeld N candle. In water-clear suspensions it is destroyed by exposure to 75° C. but not 65° C. for 30 minutes. In 50 per cent. glycerol Locke solution in the ice-chest it survives for 1-2 years at least.

HODGKIN'S DISEASE (LYMPHADENOMA)

Little is known of the aetiology of this fatal disease, in which characteristic histological changes are usually found in the enlarged lymph glands and lymphoid deposits. Gordon (1933, 1934, 1936) described the reproduction of meningo-encephalitis in rabbits by the intracerebral inoculation of autolysed gland suspensions. Elementary bodies are said to be distinguishable in human material and in impression preparations of infected rabbit's brain. Gordon's test is said to be of diagnostic value in about 75 per cent. of cases of Hodgkin's disease (van Rooyen 1934, 1937a). The encephalitogenic agent is said to pass through British Berkefeld and Seitz EK filters; to be inactivated by exposure to a temperature of 80° C. for 30 minutes; to withstand 0.5 per cent. phenol at 37° C. for probably a week

mechanisms for carbohydrate metabolism—that is, the facultative anaerobes. Early in his studies on the fermentative activities of microorganisms, Pasteur observed that the anaerobic fermentative breakdown of carbohydrate is lessened in the presence of oxygen. Many years later, Warburg called this phenomenon the Pasteur effect or Pasteur reaction.⁶³ The Pasteur effect has been studied extensively by Meyerhof, Warburg, Lipmann and many others, who have found that oxygen inhibits fermentation in almost all facultatively anaerobic cells, whether they are bacteria, yeasts, or the cells of higher plants and animals. The value to a facultative anaerobe of such a regulatory mechanism is obvious. By means of the Pasteur effect, the anaerobic fermentative breakdown of carbohydrate is blocked in the presence of oxygen, and energy is furnished by the far more efficient aerobic oxidation of carbohydrate. However, the actual mechanism of the Pasteur effect is far from obvious and is still the subject of spirited controversy. At present, it is generally believed that anaerobic fermentation is not inhibited by aerobic respiration but by the direct action of molecular oxygen upon some portion of the anaerobic breakdown mechanism.

NITROGEN METABOLISM⁶⁴

The metabolism of nitrogenous compounds by bacteria is less well understood than that of the carbohydrates, and the decomposition of these compounds is somewhat more complex in that the ring structures of the aromatic amino acids make their breakdown a series of special cases. In general, the decomposition of proteins and amino acids is of less quantitative importance in the processes of respiration except in certain cases such as that of the obligate anaerobes. The metabolism of these compounds is of no less importance, however, and the significance of the mechanisms of synthesis, which are intertwined with those of carbohydrate synthesis, is becoming increasingly clear, not only in relation to particular questions such as that of the mechanism of action of the chemotherapeutic drugs, but also in that the microorganisms have certain unique advantages in the investigation of the general biological problems of anabolism.

The Hydrolysis of Proteins. The ability to make use of amino acids is widespread among the bacteria, with the formation of compounds such as hydrogen sulfide, indol, amines and the like which are associated with the decomposition of proteins. The ability to hydrolyze native proteins to their amino acid constituents is, however, one that is possessed by relatively few kinds of bacteria. The limited occurrence of this capability is sufficiently marked that it is customary to speak of bacteria as fermentative or proteolytic in type according to whether carbohydrate oxidation or proteolysis characterizes their biochemical activities.

As compared with knowledge of the proteolytic enzymes of higher organisms, very little is known of the bacterial proteases.⁶⁵ In general they appear

The Hydrolysis of Proteins

to be tryptic in nature, i.e., they act in slightly alkaline media, whereas in protozoa and probably in fungi, pepsin-like enzymes occur. It is probable that a number of proteolytic enzymes are possessed by bacteria analogous to those occurring in higher organisms. Available evidence indicates, for example, that decomposition may be carried to the polypeptide stage by one or more enzymes, while further dissolution is accomplished by means of another enzyme or group of enzymes.

The bacterial proteases are, for the most part, extracellular enzymes which are diffused into the medium and are present in sterile filtrates of cultures. Presumably protein molecules are too large to diffuse into the bacterial cell and are partially hydrolyzed outside. Split products probably diffuse into the cell to be further decomposed. Intracellular bacterial proteases have, however, been found⁶⁶

Of the bacterial enzymes the proteases appear to be the most markedly affected by the medium upon which the organisms producing them are grown. Chief among the factors influencing their production is the nitrogenous material present in the medium, in general, highly active filtrates may be obtained only from cultures in protein-containing media, although the detection of proteolytic activity in cultures grown in some of the so-called "synthetic" media containing no protein material indicates that the presence of substrate is not essential to the formation of the enzymes. The inorganic salts present are also of importance. It has been shown, for example, that the presence of magnesium and calcium salts is necessary for the production of gelatinase, the former stimulating growth but the latter actively stimulating the production of the enzyme. Undoubtedly a series of other environmental factors affect the production of proteolytic enzyme, but present knowledge is extremely fragmentary.

The ability to liquefy gelatin, a character of considerable value in the biochemical differentiation of bacteria, is often taken as indicative of the proteolytic potentialities of these organisms. Many organisms, however, which liquefy gelatin are unable to break it down further to amino acid units which may be used. *Staphylococcus aureus*, for example, although liquefying gelatin, is unable to hydrolyze the protein to abiuret substances and, presumably, can neither assimilate nor oxidize this substance. The digestion of gelatin by actively proteolytic organisms such as *Proteus vulgaris* is, on the other hand, carried rapidly to the amino acid stage, and evidences of the further decomposition of the amino acids, such as the liberation of ammonia, soon appear.

The resistance of pure native proteins, coagulated proteins and even purified protease to attack by actively proteolytic bacteria in the absence of other food materials is well established. Such bacteria, inoculated into a mineral salt solution containing a pure protein such as crystalline egg albumin, do not multiply but in time die off. If, however, a small amount of peptone or meat extract is added to such a medium, the bacteria grow well and decompose the pure protein in a normal way. It is probable that extracellular protease inoculated with the bacterial cells is thereby so diluted that no hydrolysis takes place and, in the absence of smaller molecules that can diffuse into the cells

⁶⁶ Allen and Cullen Jour. Exp. Med., 1920, 32:547, 571.

distribution. If our knowledge was more extensive than it is, we should probably be able to describe a basal flora, characteristic of mankind under all conditions; a supplementary flora, varying in frequency, but ranging widely as normal parasites of man; and various species showing a restricted range or a temporary prevalence, conditioned by localized or transient environmental factors. This aspect of bacterial ecology has, however, received but little attention, except with regard to the incidence of a few important pathogenic species. If we include, among the normal flora of a particular region of the body, all those bacterial species which may be isolated from any considerable sample of apparently healthy persons, we must note that this flora varies widely, from time to time, and from place to place.

The nature of the intestinal flora, for example, depends on a number of factors, such as diet, gastric acidity, degree of peristalsis, external temperature, and so on. The predominant flora on a herbivorous differs from that on a carnivorous diet; in the upper part of the small intestine it is more copious in persons with gastric hypoacidity than in normal persons. Again, the flora of the nasopharynx is constantly changing both in the same individual and in the same community. At one time, pneumococci and Pfeiffer's bacilli may be present in large numbers in apparently healthy persons, whereas at another time they may be far less frequent. It must be realized, therefore, that, in the account which follows, we can make no attempt to give a complete description of the organisms that may be found in different parts of the body, or to indicate more than roughly their frequency and relative proportions.

The species found in the regions of the body which are normally colonized by bacteria include those generally accepted as pathogens, those generally accepted as saprophytes, and many that are intermediate. We know very little of the nature of the association between the bacterium and the healthy host tissue in any of these three groups. We may regard all typical members of a pathogenic species as virulent, and postulate a high level of immunity, perhaps specific, in order to explain the prevalence of the organism in the normal flora; or we may postulate a wide variation of virulence in the species, and assume a lesser virulence for the strains found in healthy tissue. For example, as we saw in Chapter 74, the "carrier" types of pneumococci appear to invade the lung tissue of carriers only when the host is subjected to debilitating influences, and the "infective" types may be carried by healthy people who have acquired an immunity to them (see, for example, Finland, Brown and Barnes 1940); and there are indications (see p. 1375) that the normal fusiform bacilli of the mouth may initiate ulcerative lesions in the mouth of vitamin-deficient animals. But except where there is an abnormally high specific antibody response to a species that occurs in the flora of normal tissues, any explanation in terms of a balance between the virulence of the "pathogen" and the resistance of the host is little more than a re-description of the observed state of affairs, though it serves to emphasize that the coexistence of bacterial with host cells is the result of an equilibrium between two sets of factors, and not merely a mutual indifference to each other's presence. And by analogy with a large number of instances of biological associations variously described as parasitism, saprophytism, commensalism or symbiosis, we may expect that the associations of saprophytes and healthy tissue cells are equally dynamic.

Moreover, equilibria exist not only between host and "normal" flora, but between the different species within the flora; and the association of various

and be broken down by enzymes concentrated there, the bacteria starve to death. Added food material such as peptone may be regarded simply as nutrient which makes possible the initiation of growth rather than as substances essential to the formation of proteolytic enzymes.

The evolution of ammonia which accompanies the bacterial decomposition of protein material is considerably curtailed if a fermentable carbohydrate is included in the protein-containing medium in which the organisms are grown. This phenomenon has been interpreted to indicate that carbohydrate exerts a "protein-sparing" effect on bacterial proteolysis analogous to its protein-sparing effect on mammalian metabolism. Precise work, however, has shown that the analogy is spurious. A diminution in ammonia found might be due to either a decreased production or an increased utilization, since ammonia is the chief source of nitrogen for the great majority of bacteria. The presence of readily available energy in the form of a fermentable sugar stimulates growth with a coincident increase in ammonia assimilated and, in consequence, the ammonia present is diminished.

The Decomposition of Amino Acids. As pointed out above, with very few exceptions, such as the autotrophic organisms, all bacteria are able to utilize amino acids, and in most cases the decomposition of amino acids present in an actively growing bacterial culture proceeds rapidly. The enzymes concerned in the primary utilization of amino acids have been studied at some length, knowledge of them is reviewed by Gale.⁶⁷ Possibly these compounds may be used directly in some cases as building stones for bacterial protein; but in most instances some type of decomposition occurs which may liberate energy to the organism, and some of its products, such as ammonia, are the starting points of bacterial synthesis. Amino acids may be broken down in a variety of ways which may be summarized as follows:

(1) *Hydrolytic decomposition* which may result in the formation of a lower fatty acid and ammonia, of an alcohol, carbon dioxide and ammonia, or of an aldehyde, a lower fatty acid and ammonia by the following reactions

which are often brought about by aerobic organisms. The decomposition to an alcohol is frequently brought about by bacteria.

(2) *Decarboxylation with the formation of the corresponding amine* (the so-called ptomaines including pentamethyldiamine or cadaverine from lysine and tetramethylenediamine or putrescine from ornithine or arginine) is brought about by a variety of bacteria.

The bacterial amino acid decarboxylases have been studied in detail by Gale.⁶⁷ He has shown that six amino acids are commonly decarboxylated, lysine, ornithine, arginine, tyrosine, histidine and glutamic acid, all having in common a free carboxyl group in the one position, a free α -amino group, a free terminal polar group, and the natural *levo* configuration. It has also

⁶⁷ Gale Bact. Rev., 1940, 4:135, Advances in Enzymology, 1946, 6:1.

than in the healthy mouth; (5) "*Veillonella*"—said to be a normal inhabitant of the saliva (Langford *et al.* 1950); (6) Gram-negative bacilli, including members of the coliform and proteus groups; (7) Spirochaetes; these are almost invariably present between the gums and the teeth; several types have been described, such as *Treponema buccalis*, *Treponema dentium*, *Treponema intermedium* (Dobell 1912), *Treponema microdentium*, *Treponema macrodentium* (Noguchi 1912), Vincent's spirillum, and Miller's spirillum. Vincent's spirillum is often present in large numbers in the healthy mouth, usually accompanied by fusiform bacilli (see Brooke 1938); (8) *Actinomyces* (see Brooke 1938, Rosebury *et al.* 1944, and Chapter 14); (9) *Fusiformis* (see Brooke 1938 and Chapter 18); (10) Pleuropneumonia-like organisms (see Smith and Morton 1951); (11) Yeasts—mainly *Candida albicans* (Todd 1937, Lilienthal and Goldsworthy 1950). The flora of the mouth consists mainly of penicillin-sensitive organisms. By the use of penicillin pastilles most of these organisms can be eliminated. They are replaced by coliform bacilli and by yeasts (see Long 1947).

The intestinal flora of the breast-fed infant is fairly simple, consisting largely of *Lactobacillus bifidus*; this bacillus in the early weeks of life may constitute 99 per cent. of the total organisms in the faeces (Cruickshank 1925). There are in addition a few enterococci and Gram-negative coliform bacilli (Tissier and Dreyfus 1925). Snyder (1940), who followed the changes in faecal flora of infants from birth until some weeks after weaning, confirmed the predominance of *L. bifidus* in breast-fed infants, but found it also in 25 per cent. of the weaned infants. Coliforms and enterococci were also present in the breast-fed, but their frequency increased with weaning, and at the same time clostridia and members of the *Fusiformis* group became characteristic features of the faecal flora. Staphylococci of both the *albus* and the *aureus* species are often present, though usually in only small numbers (see Crowley *et al.* 1941, McFarlan *et al.* 1949, Martyn 1949, Buttiaux and Pierret 1949). They are probably derived from the infant's nose and from the mother's milk.

The intestinal flora of bottle-fed infants is not so simple. *L. bifidus* is uncommon; on the other hand, another member of the aciduric group of bacteria—*Lactobacillus acidophilus*—is usually present in large numbers (Tissier 1900). Different types of coliform bacilli, enterococci, Gram-positive aerobic spore-bearing bacilli and anaerobic bacilli, occur more or less abundantly. Two moderately pathogenic clostridia, *Cl. caputovale* and *Cl. difficile*, were first discovered in the stools of normal infants (Snyder and Hall 1935, Hall and O'Toole 1935, Snyder 1937).

In the adult, numerous workers have found that the empty stomach is generally sterile. Immediately after a meal it contains numerous organisms, which have been ingested with the food; but these, with the exception of acid-resistant vegetative bacilli and sporing bacteria, appear to be killed off rapidly. If, however, the motility of the stomach is excessive, or the acidity is below normal, this sterilizing effect of the gastric juice is probably incomplete. Thus in cases of gastric disease—particularly of carcinoma—sarcinae, saprophytic bacilli, and other organisms may actually multiply in the stomach (Goodsir 1842, Oppler 1893). In the healthy adult the jejunum and upper ileum are practically sterile. How far this is attributable to the continuing effect of the gastric juice and how far, as Cregan and Hayward (1953) suggest, to some other antibacterial mechanism, it is at present impossible to say. In the lower ileum bacteria are often to be found.

been reported that aspartic acid is decarboxylated to β -alanine in symbiotic nitrogen fixation, and the decarboxylation of tryptophane has been reported also. It is of interest that pyridoxal phosphate is a coenzyme for the decarboxylases studied by Gale.

(3) Reductive deamination with the formation of saturated fatty acids and ammonia

or

with the formation of the saturated hydrocarbon. These reactions are brought about by anaerobic bacteria which may, for example, decompose glycine to acetic acid and ammonia, or methane, carbon dioxide and ammonia.

(4) Deamination and desaturation at the α - β linkage with the formation of the unsaturated fatty acid and ammonia

is also carried out by anaerobic bacteria.

(5) Oxidative deamination with the formation of ammonia, carbon dioxide and a fatty acid of one less carbon is brought about by aerobic organisms.

(6) Anaerobic oxidative deamination accompanied by the evolution of hydrogen and the disruption of the amino acid molecule has been described. The products of decomposition of glutamic acid have been determined

reaction probably proceeds by stages which are yet unknown. This type of decomposition is sometimes known as the "fermentation" of amino acids.

(7) The mutual oxidation and reduction of pairs of amino acids resulting in deamination and decomposition, undoubtedly an important source of energy to some obligate anaerobes and possibly facultative and aerobic organisms as well. Glycine, for example, is reduced to acetic acid and ammonia, and alanine oxidized to acetic acid, carbon dioxide and ammonia

The reactions are, of course, an oxidative and a reductive deamination respectively, but the significance lies in the fact that one amino acid may act as hydrogen acceptor in the oxidation of another. The paired oxidation-reduction of amino acids has been noted earlier in connection with respiration.

The aromatic amino acids are usually attacked first at the side chain, while the ring may or may not be broken. A number of organisms decarboxylate histidine to the physiologically active substance histamine and carry the decomposition no further. The breakdown of tryptophane to indol by some bacteria and not by others is taken advantage of in the biochemical differ-

found that *Chromo. prodigiosum* introduced by fistulæ into different parts of the intestine disappeared just as rapidly as when given by the mouth and made to pass through the stomach. Estimations of pH at different levels showed that the stomach contents had a pH approximately of 4-5, the duodenal of 6-7, the jejunal of 6-7.5, the ileal of 6-7, the cæcal of 5-7, and the descending colon of 5.5-7. In experiments *in vitro* a pH of about 4 was required to bring about a rapid reduction in the number of these organisms. This pH was met with only in the stomach. If, therefore, bacterial destruction occurs as rapidly in the intestine of the monkey as in the stomach, it is clear that acidity cannot be solely responsible. Bergeim described two antibacterial mechanisms in the cæcal contents of rats and man, one dependent on volatile fatty acids—formic, acetic and butyric—the other on H_2S . At the pH of the cæcal contents, butyrate from a high butter fat diet was found to act slightly on *L. acidophilus* or yeasts, and more strongly on *Bact. coli*, *Proteus vulgaris*, and salmonellæ. If rats on this diet were given $CaCO_3$ to raise the pH of the intestinal contents, the proportion of *Bact. coli* in the faeces increased. In concentrations that occurred naturally in the cæcum of rats and man, H_2S killed yeasts, and inhibited *Bact. coli* to some extent, but hardly affected *L. acidophilus* or the enterococcus (Bergeim 1940, Bergeim *et al.* 1941).

Provisionally we may conclude that in healthy persons the majority of the organisms ingested in the food and swallowed with the saliva are destroyed in the stomach by the gastric juice. The few surviving bacteria that pass through unharmed find the conditions in the duodenum and upper jejunum too acid to allow them to multiply. With their further passage down the intestine, they encounter progressively more alkaline conditions, and are able to proliferate accordingly (see Chapter 45).

The variations of intestinal flora within mammalian species may be very great. For example, the normal flora of the guinea-pig intestine was found by Crecelius and Rettger (1943) to be fairly simple; a lactobacillus resembling *L. acidophilus* constituted approximately 80 per cent. of the total cultivable flora, the remainder being accounted for chiefly by soil and air bacteria, yeasts, and an anaerobic sarcina. Coliform organisms and enterococci were seldom present. Again, according to Porter and Rettger (1940) the flora of the white rat on a normal mixed diet consists mainly of lactobacilli and coliform organisms; very few cocci are found. Lactobacilli were common in the stomach, where little else but yeasts were demonstrable. The bacterial content of the duodenum and jejunum was low, and no lactobacilli were present. Coliforms and lactobacilli were present in the lower parts of the small intestine, and abundant in the large intestine, where spore-bearing anaerobes also appeared. The lactobacilli were generally reduced by meat, to some extent by other types of high protein diet, and by several days' starvation. Except in the lower gut, it may be noted, there was little correlation between the pH of the gut contents and the predominating flora.

Origin of the Alimentary Flora.—Witkowski (1935), investigating the origin of the mouth flora, found that organisms could be demonstrated in the mouths of 49 out of 50 infants shortly after birth. These comprised mainly *Staph. albus*, coliform bacilli, Döderlein's bacillus, and streptococci. Examination of vaginal swabs from the mothers showed that these organisms were all present in the vagina in proportions corresponding fairly closely to those in the infant's mouth. It seems probable, therefore, that the initial flora of the infant's mouth is derived from the vagina of the mother. By 2-5 days after birth other organisms had appeared consisting, in decreasing order of frequency, of pneumococci, hæmolytic staphylococci, various types of streptococci, Friedländer bacilli, corynebacteria, sarcinae, and Gram-negative cocci. Comparison of these findings with the mouth flora

entiation of many species from one another. Tyrosine may be decomposed to phenol or broken down completely, and a number of organisms break the pyrrolidine ring of proline without difficulty. Owing to differences in ring structure, the decomposition of the aromatic amino acids becomes a series of special cases which cannot be considered further here.

The types of amino acid breakdown outlined above represent a generalization. No single amino acid has as yet been shown to undergo all of the decompositions nor is any single bacterial species capable of bringing about all of these transformations. On the other hand, the bacterial decomposition of an amino acid often involves not a single type of breakdown alone but a series of reactions consisting of several of these types. The nature of the products formed is dependent, to some degree, upon oxygen tension; some compounds such as hydroxy acids may be formed under aerobic conditions but are unstable under anaerobic conditions. The pH of the medium is also of considerable importance; for example, deamination occurs at an alkaline reaction and decarboxylation at an acid reaction. The fact that ammonia is almost always liberated is of considerable significance, for ammonium salts are utilized as a source of nitrogen by the great majority of bacteria.

Aerobic and anaerobic protein decompositions are often differentiated by the terms decay and putrefaction. Superficially there would appear to be some justification for regarding the two as separate processes—the justification being largely a matter of the unpleasant odors associated with the reduced products of anaerobic decomposition as contrasted with the lack of odor of the oxidized end products of the aerobic decomposition. Such a distinction has no reality, however, for the processes of decomposition are essentially the same in both cases. Both involve preliminary hydrolysis to amino acids and have further breakdown mechanisms in common. Oxidative deamination, for example, is commonly associated with aerobic organisms, but it also occurs in the oxidation-reduction of pairs of amino acids, a reaction brought about by many of the obligate anaerobes.

Synthesis of Nitrogen Compounds. Not only the autotrophic bacteria but also the most fastidious of the heterotrophes utilize ammonia and ammonium salts as sources of nitrogen. Although, as will appear, amino acids are assimilated directly, they also serve as a source of ammonia through preliminary deamination. The ammonia is taken up and used in the synthesis of amino acids, which are in turn condensed to form proteins.

Until relatively recently little has been known of the methods of synthesis of amino acids. The significance of the anabolic phase of carbohydrate metabolism has been discussed earlier and, as pointed out there, it seems probable that the formation of carbon chains and organic acids, of which keto acids are possibly the most important, constitutes an early stage in amino acid synthesis. Furthermore, the products of glycolysis, particularly pyruvic acid, may also be sources of starting material in amino acid formation. The next stage in synthesis is, of course, the addition of amino groups.

Of the enzyme-catalyzed deaminations, only two, catalyzed by aspartase and glutamic acid dehydrogenase, have been found to be reversible. It would appear, however, that a variety of amino acids could be synthesized from the corresponding keto acids by transamination, the amino group being donated

It is easy to pass from the conclusion that bacteria are unnecessary for the human organism to the conclusion that they are actively harmful. This is a transition that has been unjustifiably made. We have no space to discuss the question of *intestinal toxæmia*. The conception that numerous cases of ill-health and of actual well-defined disease processes are due to the absorption, from the intestine, of toxic products elaborated by proteolytic micro-organisms is a plausible one, but one that rests largely on unproven assumptions. It is the almost complete lack of experimental evidence that renders the discussion of this subject so fruitless at the present time (see Discussion 1913, Dudgeon 1926).

The earliest method attempted, in efforts to prevent the possible absorption of toxins from the intestine, was the replacement of the putrefactive flora—anaerobic spore-bearers such as *Cl. sporogenes*, *Cl. putrificum*, and *Cl. histolyticum*; aerobic spore-bearers such as *B. mesentericus*; and organisms such as *Proteus vulgaris* and *Ps. pyocyanea*—by an organism of the aciduric group known as *Lactobacillus bulgaricus*. These attempts failed completely. It has since been found impossible to implant this bacillus in the normal intestine; the conditions for its growth are unfavourable. Experimental work has shown that, in order to encourage the growth of a given type of organism in the intestine, it does not suffice to administer such an organism by the mouth, but that it is also essential to give by the mouth a sufficient quantity of a selective food material to enable it to flourish at the expense of other organisms. The replacement of a proteolytic by a saccharolytic flora—aciduric bacilli, *Cl. welchii*, and the enterococcus—can be largely accomplished by feeding on a high carbohydrate diet. In rats it has been found that by giving large quantities of lactose or dextrin in the diet, the intestinal flora can be so changed that it contains 90 per cent. or more of aciduric bacilli (Rettger and Cheplin 1921, Cannon and McNease 1923, Cruickshank 1928). These two carbohydrates are absorbed very slowly, and consequently pass into the large intestine. They are there acted upon by the aciduric bacilli—notably *L. acidophilus*—with the formation of a large amount of lactic acid; the presence of this acid is unfavourable to the persistence of the proteolytic bacteria. Without the supply of lactose, dextrin or milk the aciduric bacilli cannot be successfully implanted in the intestine, even though pure cultures are given in large quantity daily. In infants 12 per cent. of lactose must be added to whole cows' milk or to lactic acid milk in order to convert the mixed intestinal flora into a lactobacillary flora similar to that found in the stools of breast-fed babies (Gerstley, Howell, and Nagel 1932).

In old people, particularly those with hypochlorhydria, the small intestine is no longer sterile, the sugar in the diet is fermented before it reaches the large gut, and the lactobacilli are unable to thrive. In consequence the *fæces* contain salivary streptococci that have not been killed off in the stomach and larger numbers of putrefactive organisms than normally, but very few lactobacilli. Any benefit to be derived by such persons from drinking Yoghurt and other types of sour milk is not, as Metchnikoff supposed, due to the ingestion of the lactobacilli themselves but to the provision of milk sugar; this is not readily broken down till it reaches the large intestine, where the acid produced inhibits the development of putrefactive bacteria (Orla-Jensen *et al.* 1945). Whether sour milk has any advantage over sweet milk for this purpose is perhaps doubtful.

This is not the place to discuss the value of changing the intestinal flora in the treatment of constipation and other disorders, but we shall refer our readers

Synthesis of Nitrogen Compounds

by a dicarboxylic amino acid. Lichstein *et al*⁶⁸ have found that a number of bacteria can carry out this reaction between glutamic acid and oxalacetic acid to give α -ketoglutaric acid and aspartic acid, between glutamic acid and pyruvic acid to give α -ketoglutaric acid and aspartic acid, and between glutamic acid and pyruvic acid to give α -ketoglutaric acid and alanine. Bacteria such as *Bact. coli* contain all the enzymes necessary to catalyze the following reactions

The intimate relation between the synthesis of glutamic acid, aspartic acid and alanine with carbohydrate metabolism is apparent. It is possible that transamination systems are a part of a general system of amino acid synthesis but it is also possible that these reactions are a part of the respiratory mechanism concerned with the metabolism of four and five-carbon acids.

There is also fragmentary evidence of amino acid synthesis from studies on bacteria which require amino acids. There has, for instance, been some study of precursors, i.e., related compounds which can be substituted for the required amino acid, and it has been found, for example, that indol can be substituted for tryptophane in the growth requirements of typhoid bacilli requiring the amino acid, suggesting that such strains are unable to synthesize the indol ring. More detailed studies with *Neurospora* mutants have shown that anthranilic acid is a precursor of indol, and that indol is condensed with serine to form tryptophane.⁶⁹ Other studies have shown that the synthesis of arginine by *Neurospora* proceeds through ornithine and citrulline.⁷⁰ Still another approach is that of inhibition of amino acid formation by other amino acids or by analogues. The toxic effect of certain amino acid mixtures for the anthrax bacillus reported by Gladstone⁷¹ has been interpreted as an inhibition of synthesis, and similar observations have been made by other workers. The inhibition of methionine and methoxinine has been studied and it has been found that ethionine formation by analogues is inhibitory, and that the inhibitory activity is antagonized by methionine. It will be clear, however, that as yet there is only fragmentary information regarding the mechanisms of amino acid synthesis. The only general principles indicated, and these are no more than suggested, are those of reversible deamination and transamination.

As yet there is little information regarding the formation of peptide chains and proteins. There is reason to believe, however, that the tendency of glutamic acid to condense into peptides, and the tendency of β -aminobenzoic acid, linked

acid, of cocarboxylase from thiamin and of riboflavin from flavoproteins, takes place in the stomach. (For short reviews of this subject see Kon 1945, Elvehjem 1948, Johansson and Sarles 1949.)

As we have seen in Chapter 54, the fact that a substantial amount of the vitamin or food requirements of an animal may be satisfied by the bacteria in its alimentary canal affects the interpretation of a good deal of recorded work on experimental variations of diet. It also throws light on the association of deficiency states with diarrhoeal syndromes, and with prolonged therapy of intestinal infections with drugs like sulphaguanidine and succinyl sulphathiazole.

Intestinal bacteria may also destroy essential foodstuffs. Thus, in the absence of a more readily fermented carbohydrate, *Bact. coli* and a number of other intestinal species will decompose Vitamin C in media containing organic nitrogen. It is not known to what extent dietary Vitamin C is destroyed in the alimentary canal, but the hypothesis of its decomposition by bacteria is in accord with the observation that certain scorbutic patients respond to injected, but not to oral, Vitamin C (Young 1942, Young and James 1942, Young and Rettger 1943). Again, nicotinic acid may be utilized as the sole source of nitrogen by organisms of the *Pseudomonas* group and by certain chromobacteria, though in the absence of nicotinic acid, these organisms synthesize the vitamin (Koser and Baird 1944; see also Benesch 1945). The production of a vitamin by the intestinal flora will clearly be determined by a multiplicity of factors, of which the presence of vitamin-producing and vitamin-destroying bacteria is only one; and the determination of these factors presents an exceedingly complex problem in bacterial ecology.

A peculiarly fascinating aspect of the relationship of bacteria to nutrition was revealed by Stokstad and his colleagues in New York (1949) when they observed that the addition of aureomycin to the diet stimulated the growth of chicks. Similar observations were made by numerous other workers on pigs, chicks, and turkey poults, using aureomycin, terramycin, or penicillin (Wahlstrom *et al.* 1950, Coates *et al.* 1951, Sieburth *et al.* 1951, Larson and Carpenter 1952). The mechanism by which this effect is produced is still in doubt. It is thought by some workers that intestinal organisms detrimental to the host are suppressed by the antibiotic, and by others that by alteration in the intestinal flora organisms producing Vitamin B₁₂ or some other factor favourable to growth are stimulated.

The Normal Flora of the Respiratory Tract.

For our present purpose we may divide the respiratory tract into three sections: an upper part, including the anterior and posterior nares and the nasopharynx; an intermediate zone, common to the respiratory and alimentary tracts, including the oropharynx and the tonsils; and a lower part, including the larynx, trachea, bronchi and lungs.

The bacterial flora of the nasal passages differs in several respects from that of the nasopharynx. It is less copious: if swabs are taken from the nose and nasopharynx of a sample of normal persons, and plated on some suitable medium, the nasal swabs will give the lower colony counts, and the differences observed are often striking. Qualitatively, diphtheroid bacilli and staphylococci—both *Staph. aureus* and *albus*—are far more frequent in the nose than in the nasopharynx, whereas *Str. viridans*, indifferent streptococci, and Gram-negative cocci of the *N. pharyngis* type, are far less frequent. These non-hæmolytic streptococci and Gram-negative cocci appear to constitute the basal normal flora of the naso-

through a pterine nucleus to glutamic acid to give the vitamin pteroylglutamic acid (folic acid), are in some way intimately related to peptide and protein synthesis. This assumes considerable significance in view of the antagonism of *p*-aminobenzoic acid for the sulfonamides, and it is possible that these drugs may act through inhibition of synthetic reactions.

The Decomposition of Fats. From the quantitative point of view fats are not an important food source for bacteria. Bacterial lipases are not uncommon, however, and the action of bacteria on fat-containing media has some use as a differential character. Following hydrolysis the glycerol is readily fermented by a wide variety of bacteria, but the ability to decompose the higher fatty acids does not seem to be common and a number of these, such as palmitic, stearic, oleic and other acids, cannot be utilized as a source of carbon by many of the well known bacteria. The oxidative decomposition of fatty acids assumes some importance with regard to the development of rancidity of fat-containing foods.

NITROGEN FIXATION⁷²

The ability to use molecular nitrogen as a nutrient is, like the oxidation of ammonia and nitrite, a property of a limited number of bacterial species. Evidence of the biological basis of nitrogen fixation was reported in 1862, and it was later shown that the increase in organic nitrogen content of uncultivated soils could be prevented by sterilization or storing at a low temperature. Following the work of Winogradsky, Beijerinck, Hellriegel and Wilfarth and others it became apparent that atmospheric nitrogen is fixed by

- (1) free-living bacteria both
 - (a) anaerobic and
 - (b) aerobic and by
- (2) bacteria living symbiotically with leguminous plants.

The anaerobic organism, *Clostridium pastorianum*, isolated by Winogradsky in 1893, was the first nitrogen-fixing bacterium to be studied in pure culture. When cultivated under anaerobic conditions in a medium containing glucose but no nitrogen, the organism grows well, obtaining its energy through the fermentation of the sugar and its nitrogen from nitrogen gas. The amount of nitrogen fixed is proportional to the amount of glucose fermented—2.4–2.9 milligrams of nitrogen fixed per gram of glucose fermented in Winogradsky's experiments. The fixation of nitrogen is inhibited by the presence of ammonium salts in the medium and may be lost through continued cultivation on nitrogen-containing media. *Cl. pastorianum* is a spore-forming rod closely related to the bacteria of the so-called amylobacter group (so-called because many of them stain blue with iodine), organisms which ferment carbohydrate to butyric acid. The chief products of the fermentation of glucose by *Cl. pastorianum* are acetic and butyric acids and carbon dioxide and hydrogen. It has been found that the ability to fix nitrogen may be "restored" to some amylobacter species by a method of "soil passage" which restores this property to strains of *Cl. pastorianum* which have lost it through prolonged cultivation.

⁷² Biochemical nitrogen fixation is reviewed by Burk and Burris, *Ann. Rev. Biochem.*, 1941, 10:587; Burris and Wilson, *Ann. Rev. Biochem.*, 1945, 14:685; Wilson and Burris: *Bact. Rev.*, 1947, 11:41.

pathogenic species to vegetate in the nose than in the nasopharynx. Mouth-washing, in this series of cases at least, appears to be a less effective method of isolating the pneumococcus and the influenza bacillus, but equally effective for the hæmolytic streptococci and the Gram-negative cocci (see also Gundel and Linden 1931, Gundel and Okura 1933, Gundel 1933).

It must not be supposed that these are constant figures. They fluctuate widely both from time to time and from place to place. Thus the nasopharyngeal carrier rate of hæmolytic streptococci may vary from zero to 20 per cent. in a sample of the normal adult population subjected to repeated swabbing. The fluctuations in pneumococci and influenza bacilli are usually smaller (see also Burky and Smillie 1929).

Table 181 summarizes the results of a large survey by Straker, Hill and Lovell (1939), which included a group of adults sampled at intervals over a period of seven years. In children, the pneumococcal carrier rates tended to be higher than those recorded in the table, but otherwise the rates were not significantly different.

TABLE 181

SHOWING THE CARRIER RATES FOR CERTAIN BACTERIAL SPECIES IN THE NASOPHARYNX AND NOSE FOR A GROUP OF ADULTS IN AN URBAN POPULATION

Organism.	Nasopharyngeal Carrier Rate	Nasal Carrier Rate.
	Per cent.	Per cent.
<i>Str. pneumoniae</i>	20-40	5-15
Hæmolytic streptococci	5-15	< 1
<i>H. influenzae</i>	40-80	5-10
<i>N. meningitidis</i>	5-20	0-4
Gram-negative cocci other than <i>N. meningitidis</i>	90-100	0-15

The rates varied to some extent with the season. In the nasopharynx, pneumococci and to a slight extent *H. influenzae* were found more frequently in cold, damp seasons than in the dry hot periods; in the nose a similar, but more definite seasonal variation occurred. There was some evidence of an association between these two organisms, whose colonization of the nasopharynx appears to be fairly constant; in the damper colder seasons, they appeared more frequently in the nose of living persons, and in the trachea of persons who had died from a variety of causes. That is, in the summer months the organism was confined largely to the nasopharynx, but in late winter and early spring it tended to colonize downwards into the trachea and forward into the nasal cavity.

The carrier rates for hæmolytic streptococci in the throat are substantially the same in other countries as in Great Britain (see, for example, Bryce and Tewsley 1938, Wu 1941, Boisvert 1942, and Chapter 66). An association of high carrier rates with the possession of tonsils, in both children and adults, has been noted by a number of workers. Thus, Burpee (1937) in an institutional survey records a rate of 27.3 per cent. in persons with tonsils, and 10.3 per cent. in those whose tonsils had been removed (see also Chesterman and Scandrett 1940, Pike and Fashena 1946). Of the hæmolytic streptococci isolated from the throat, a large proportion belong to Lancefield's Group A. The proportion varies from 20-70 per cent (see, for example, Fleming 1939, Pomales-Lebrón 1940, Williams and Harper 1944), some of the remainder belonging to Lancefield's other groups. It is noteworthy that Group A streptococci colonize the tonsils more readily than other hæmolytic

Nitrogen Fixation

on laboratory media. It is probable that all these organisms constitute a relatively homogeneous group whose natural habitat is soil

The aerobic nitrogen-fixing bacteria were discovered by Beijerinck in 1901 and named by him *Azotobacter*. Two species were originally suggested: *Azotobacter chroococcum*, a pigmented (deep brown to black), nonmotile organism found predominantly in soil, and *Azotobacter agilis*, a motile form producing a soluble green pigment and found in water. Two other species have been found in this country, *Azotobacter vinelandii* and *Azotobacter beijerinckii*. Although one or two additional species have been described, these four have until recently, been the generally recognized members of the genus *Azotobacter* as typical of the group. This species has a world wide distribution; the other three are apparently more restricted although *A. agilis* may have a wider distribution than formerly thought. All fix nitrogen in alkaline

fig. 19. *Azotobacter chroococcum*. Three-day culture on nitrogen free dextrose medium Nigrosin relief preparation, $\times 978$ (Starkey)

environments, fixation proceeding most rapidly at pH 7.0 to 7.5. Starkey⁷¹ has reported the isolation of a species designated as *Az. indicum* from acid soil which fixes nitrogen when grown in an acid (pH as low as 3.0) medium. *Azotobacter* survives for long periods of time, as long as twenty years, and still is able actively to fix nitrogen.

In addition to reaction, a number of other factors govern nitrogen fixation by these organisms. Phosphate, calcium and oxidizable carbon compounds (mannitol or propionate are usually supplied in laboratory media), in addition to certain metals such as iron and molybdenum,⁷² are necessary for fixation, and the numbers of these organisms in a given soil may often be increased by the addition of chalk, lime, phosphate or carbohydrate, depending upon the deficiencies of the particular soil.

Like *Cl. pasteurianum*, *Azotobacter* does not fix nitrogen in the presence of adequate amounts of nitrogen compounds in the medium but, unlike the anaerobe, does not lose the ability to fix nitrogen through continued cultivation.

⁷¹ Starkey: Science, 1939, 89 267. See also Starkey and De Soil Sci., 1939, 47 329
⁷² Cf. Burk. Ergebnisse der Enzymforschung, 1934, 3 23

and 24 months (see also Ludlam 1953). Observations made by numerous workers suggest that in maternity units infants become infected with *Staph. aureus* more often from nurses and from the dust of the nursery than from their mothers.

Various workers have described the presence of small Gram-negative, filter-passing, anaerobic bacilli, in suspensions obtained by washing out the nares, nasopharynx and oropharynx with sterile broth (Olitsky and Gates 1921a, b, Olitsky and McCartney 1923, Mills, Shibley and Dochez 1928, Garrod 1928, Burky and Freese 1931). The evidence suggests that these strains may be differentiated into several distinct types; but they have not yet been submitted to detailed study from the systematic point of view. The so-called "*Bacterium*" *pneumosintes*, at one time regarded as a possible cause of epidemic influenza, apparently belongs to this group. The information at present available on the relative frequency of these bacilli in normal persons, and in those suffering from colds, does not indicate that they play any significant rôle in such infections. Garrod (1928) also described the isolation, by the same technique, of minute, Gram-negative, filter-passing, anaerobic cocci.

The Normal Flora of the Vagina.

An important distinction must be drawn between the flora of the vulva and vestibulum on the one hand and that of the vagina proper on the other. Except immediately after parturition and during the first few days of the puerperium, the vaginal flora is quite distinct from that of the vulval flora.

The *vulva* of the newly-born child is sterile; organisms make their appearance in about 7 to 8 hours. The normal flora of the vulva is a rich and varied one, and depends largely on the organisms present in its immediate environment. According to Wegelius (1909) it consists of: (1) Obligatory aerobes and aerophilic bacteria, of which the chief types are pseudo-diphtheria bacilli and *M. tetragenus*. (2) Coliform bacilli. (3) Facultative anaerobes, usually more or less susceptible to acid. (4) Bacilli derived from the vagina, including yeasts. (5) Obligatory anaerobes. On agar plates incubated aerobically the commonest organisms to form colonies are staphylococci, diphtheroids, enterococci, sarcinae, and coliform bacilli. Besides these organisms, yeasts—*Oidium* and *Saccharomyces*—are very common; and the smegma bacillus is not infrequently demonstrable in smear preparations stained with Ziehl-Neelsen. Under anaerobic conditions of cultivation numerous colonies appear, consisting of organisms that have as yet been only imperfectly studied. Pathogenic bacteria are uncommon.

The normal flora of the *vagina* seems to depend largely on the glycogen content of the vaginal epithelium which, in its turn, is dependent on ovarian activity (Miura 1928, Cruickshank and Sharman 1934). The vagina of the newly born child is sterile; organisms make their appearance in 12-24 hours. At first they consist of staphylococci, enterococci, and diphtheroids, but these are often replaced in 2 or 3 days by a practically pure culture of Döderlein's bacillus (see Chapter 31). At this time glycogen is demonstrable in the vaginal epithelium, and the vaginal secretion itself is acid. The occurrence of glycogen appears to be due to the presence of œstrin derived from the maternal circulation. Soon this is excreted in the urine glycogen is no longer demonstrable in the epithelium,

tion on nitrogen-containing media. Although *Azotobacter* fixes nitrogen in the free-living state, it is not infrequently found in nature living symbiotically with higher plants. *Chlorella*, for example, may grow in association with the bacterium, the former assimilating carbon dioxide and the latter molecular nitrogen.

The mechanism by which nitrogen is fixed is obscure. Winogradsky suggested that *Cl. pastorianum* might bring about a direct combination of nitrogen with nascent hydrogen liberated in the fermentation of glucose to form ammonia. It has been generally supposed that the fixation of nitrogen is an endothermic process, but Burk⁷⁵ has pointed out that fixation might take place by means of exothermic reactions either in the presence of hydrogen arising from the fermentation of glucose or formate, or as an oxidation in the presence of free oxygen.⁷⁶ Wilson and Burris⁷² have reviewed more recent evidence

Fig. 20. Colonies of *Rhizobium radicicola* on nutrient agar. Twenty-four hour culture, $\times 3$.

regarding the mechanism of fixation and conclude that ammonia is the most likely intermediate, arising from the reduction of nitrogen by substrate hydrogen. As in other phases of bacterial chemistry, the temptation to assume a free radical chemistry is strong, but there is as yet insufficient evidence to justify such an assumption.

The efficiency of the fixation process is variable depending upon the partial pressure of oxygen. The high respiratory rate of *Azotobacter*, $QO_2 = 2000$ to 4000, the highest recorded for any living cell, is at a maximum at 10 to 15 per cent oxygen, falling off sharply on either side of this optimum. Maximum nitrogen fixation, however, takes place at 4 to 5 per cent oxygen, and the efficiency of the fixation process increases with decreasing oxygen pressure. Under optimum conditions nitrogen is fixed with an efficiency of approximately 11 per cent of the maximum theoretically attainable, a figure which falls off to about 1 per cent under atmospheric conditions.

⁷⁶ An oxidation to HNO_3 . If the concentration of HNO_3 is less than 0.1 molar, ΔF has a positive value.

human beings and to rabbits, but potentially pathogenic *Staph. aureus* is not infrequently found (Koch 1908). In moister parts, like the axillæ and inguinal folds, Gram-negative bacilli often predominate.

Staph. aureus is not uncommon on the skin of the face and hands, but less common on other parts of the body. The numbers present are usually small, but carrier rates of 5-24 per cent. have been recorded (Vierthaler 1940, Bartley 1941, Smith 1941, Martin 1942). Skin carriage is usually associated with nasal carriage. In our observations on over 1,000 normal adults 24.7 per cent. of nasal carriers were skin carriers, and 87.3 per cent. of skin carriers were also nasal carriers (Miles *et al.* 1944). As shown by serological or bacteriophage tests, the types of staphylococci found in the nose and skin are usually the same (Gillespie *et al.* 1939, Miles *et al.* 1944, Williams 1946). To some extent, therefore, it appears that the skin is continually being infected with *Staph. aureus* from the nose. This conclusion is supported by the finding that reduction of nasal carriage by topical treatment with penicillin leads to a significant reduction in the proportion of skin carriers (Moss *et al.* 1948). Though *Staph. aureus* is usually transient in Price's sense, some persons carry this organism so deeply in the recesses of the skin that prolonged sweating is required to bring it to the surface (Devenish and Miles 1939). In such persons it may be regarded as part of the resident flora (see also Gillespie *et al.* 1939, Vierthaler 1940).

In Chapter 66 we have discussed *Str. pyogenes* as an occasional transient member of the skin flora. There is no reason to believe that it ever forms part of the resident flora of the clinically normal skin; and indeed, in the light of Burtenshaw's (p. 142) demonstration of natural fatty antistreptococcal substances in the normal skin, it seems unlikely that it could ever do so.

Among other organisms met with are occasional coliform organisms, *Proteus*, and diphtheroids. Horwood and Minch (1951) were able to isolate coliform organisms from 22 out of 34 food handlers, of the 22 positive samples, *Bact. coli* was present alone or with other members of the group in 13. Diphtheroids are probably located mainly in the sebaceous glands. The healthy skin appears to have some natural self-disinfecting mechanism which is responsible for the rapid disappearance of living organisms implanted upon it (see Chapter 45 and Colebrook and Maxted 1933, Arnold and Bart 1934).

In the skin lining the external auditory meatus, as well as the usual staphylococci, diphtheroid bacilli are not uncommon, and sometimes saprophytic acid-fast bacilli, derived from the cerumen, are met with. In the conjunctival sac, organisms are comparatively scanty, and consist chiefly of diphtheroids, such as *C. xerose*. The conjunctiva may owe its comparative freedom from bacteria, in part, to a highly potent lytic enzyme, called by Fleming and Allison (1922) *lysozyme*. These workers found that tears have a high bactericidal power, capable of dissolving certain saprophytic cocci in a dilution of 1/40,000. Further study showed that, with the exception of cerebrospinal fluid, sweat, and urine, this enzyme is distributed to a greater or less extent in practically all the human secretions and tissues, as well as in animal and some vegetable tissues.

Testing the bactericidal power against a large non-pathogenic coccus, called by them *M. lysodeikticus*, they found the blood serum active in a dilution of 1/270, nasal mucus and sputum in 1/13,500, and saliva in 1/300. Extracts of tissues made by grinding up 1 gm. of tissue with 20 ml. of saline showed that the liver and the tonsil were active at a dilution of 1/400, the kidney and skin at about 1/100, while cartilage was active

The Symbiotic Nitrogen-Fixing Bacteria

The Symbiotic Nitrogen-Fixing Bacteria. The enrichment of a soil by the cultivation on it of leguminous plants such as soy beans, vetch, peas, clover and the like has been known throughout recorded history. Although such plants were early (1838) shown to take up atmospheric nitrogen, the relation between nodule formation and nitrogen fixation was first conclusively demonstrated by Hellriegel and Wilfarth in 1888 and the bacteria present in the nodules were cultivated by Beijerinck in the same year. These organisms, called by him *Bacillus radicumicola* and now known under the generic name of *Rhizobium*, were shown through subsequent work to fix atmospheric nitrogen when living symbiotically in the root nodules. Although the bacteria occur free in the soil, nitrogen is not fixed except in intimate association with the host plant.

Fig. 21. *Rhizobium leguminosarum* Smear from a pure culture; fuchsin, $\times 1050$.

The bacteria in pure culture on artificial media are small, motile rods which do not form spores. They show a high degree of pleomorphism in the root nodules, however, small oval forms and branching forms (*bacteroides*) are found admixed with the rod forms. Some workers regard these bacteria as a single species, *Rhizobium leguminosarum*, which is made up of a variety of strains differing from one another immunologically and in their ability to infect the various species of leguminous plants. These strains fall into two groups, however, one having peritrichous flagella and being somewhat more active biologically than the other, which has monotrichous flagella. Bergey (1948) recognizes six species of *Rhizobium*, viz., *Rh. leguminosarum* (legumes), *Rh. phaseoli* (beans), *Rh. trifolii* (clover), *Rh. lupini* (lupine), *Rh. japonicum* (soy beans), *Rh. meliloti* (clover). *Rh. radicumicola* is regarded as synonymous with *Rh. leguminosarum*. As a group they appear to be closely related to *Bacterium aerogenes*, Friedlander's bacillus and similar organisms. An organism known as *Bacterium radiobacter* is often found associated with the nodule bacteria but does not fix nitrogen.²²

²² For a study of this organism see Hofer Jour. Bact. 1941, 41:193

(3) With avirulent bacteria, which have little power of multiplication within the tissues, this mechanism results in a rapid and permanent clearing of the circulation. With virulent bacteria an initial partial clearing is followed by a stage of bacterial multiplication in the foci to which the bacteria have been removed, resulting in a secondary invasion of the blood stream. The fate of the host is determined by the balance between this bacterial multiplication and the efficiency of the clearing mechanism. With slightly or moderately virulent strains there is a secondary bacteræmia followed by a secondary clearing. With highly virulent strains the secondary bacteræmia increases and the animal dies of an acute septicæmia. Even when secondary clearing occurs, and the animal remains in apparent health, foci of infection may remain in the various histiocyte depôts, and living bacteria may persist in these situations over long periods of time.

(4) When bacteria get into the body by other routes they are dealt with in part by local mechanisms of the same general character as that described under (3). The extent to which invasion of the blood stream occurs depends upon the anatomy and functional activity of the tissues first invaded, and upon the virulence of the invading organism. The blood stream is invaded very rapidly after intraperitoneal inoculation, less rapidly after intramuscular inoculation, and still less rapidly after subcutaneous inoculation. In all cases the passage of the invader from the primary lodgment to the blood stream is mainly by way of the lymphatics, and the histiocyte depôts in the regional lymphatic glands play a prominent part in the removal of the invading bacteria. When relatively avirulent bacteria gain access to the tissues at some site from which passage to the blood stream is slow, infection may never pass beyond the first line of defence in the regional lymphatic glands, but here, as in the case where a generalized infection has become established, localized foci of infection may persist over long periods of time.

(5) In addition to this process of removal and digestion by phagocytic cells, a direct bactericidal action of the serum plays a part in ridding the tissues of bacteria. The importance of this purely humoral immunity appears to differ widely in different bacterial infections; but it is probably always subsidiary to the phagocytic mechanism, and is seldom, if ever, the main factor in defence.

(6) The efficiency of the clearing mechanism of a normal animal may be increased, *vis-à-vis* a particular bacterial parasite, by active immunization with a killed culture of that particular organism. The immunity so produced is specific in the serological sense. The actively immunized animal deals with a virulent strain of the bacterium against which it has been immunized in the same way as a normal animal deals with an avirulent or slightly virulent strain of the same bacterial species.

(7) Immunity of this type may be passively transferred by the injection into a normal animal of the serum obtained from an animal that has been actively immunized.

(8) The antibodies by which this passive immunity is conferred are those that unite with the surface antigens of the virulent bacteria; and in order to induce an effective active antibacterial immunity the immunizing agent employed must contain these surface antigens.

(9) The efficacy of humoral immunity in any part of the tissues is determined in the first place by the existing concentration of antibody on the cells or in the tissue fluid, and the availability of circulating antibody; and secondly by the presence, in optimal amounts, of the reactants, both fluid and cellular, necessary

Rhizobium occurs only in association with the host plant, the mechanism of fixation is somewhat better understood than in the case of the free-living nitrogen fixers, chiefly through the work of Virtanen and his colleagues. It has been found that not inconsiderable quantities of nitrogen are excreted by the root nodules during the early stages of growth in the form of glutamic and aspartic acids and β -alanine together with a small quantity of the oxime of oxalacetic acid. It appears that nitrogen is fixed as hydroxylamine, which in turn condenses with oxalacetic acid supplied by the plant. The oxime is then reduced to aspartic acid, which serves as a starting material for the synthesis of other amino acids. The occurrence of glutamic acid has been taken to suggest that hydroxylamine is also reduced to ammonia, but is also compatible with the assumption that nitrogen is fixed as ammonia. The β -alanine found presumably arises through decarboxylation of the aspartic acid. The course of the fixation process may be expressed thus:⁷⁸

Plants other than the leguminosae show nodule formation which, in some cases, is associated with nitrogen fixation. A number of species of alder (*Alnus*), for instance, have root nodules and there is evidence that nitrogen fixation occurs. Nodule formation is not confined to roots: some plants, the Rubiaceae and Dioscorea, show bacteria-containing nodules on the leaves, and in one instance these have been shown to fix atmospheric nitrogen.

It is open to question whether bacteria other than those described above are able to fix nitrogen. Fixation has been reported for a variety of organisms such as the pneumococcus, but the evidence is inconclusive and fragmentary. It has been shown,⁷⁹ however, that the blue-green alga *Nostoc* is able to fix atmospheric nitrogen.

THE NUTRITIVE REQUIREMENTS OF BACTERIA⁸⁰

It is already apparent that bacteria as a group include a wide variety of physiological types, ranging from the photosynthetic and autotrophic forms to those which metabolize carbohydrates and organic nitrogenous substances by means of complex enzyme systems. The food requirements of these organisms are equally diverse, some being able to utilize inorganic compounds of carbon and nitrogen while others require organic compounds of varying de-

human beings and to rabbits, but potentially pathogenic *Staph. aureus* is not infrequently found (Koch 1908). In moister parts, like the axillæ and inguinal folds, Gram-negative bacilli often predominate.

Staph. aureus is not uncommon on the skin of the face and hands, but less common on other parts of the body. The numbers present are usually small, but carrier rates of 5-24 per cent. have been recorded (Vierthaler 1940, Bartley 1941, Smith 1941, Martin 1942). Skin carriage is usually associated with nasal carriage. In our observations on over 1,000 normal adults 24.7 per cent. of nasal carriers were skin carriers, and 87.3 per cent. of skin carriers were also nasal carriers (Miles *et al.* 1944). As shown by serological or bacteriophage tests, the types of staphylococci found in the nose and skin are usually the same (Gillespie *et al.* 1939, Miles *et al.* 1944, Williams 1946). To some extent, therefore, it appears that the skin is continually being infected with *Staph. aureus* from the nose. This conclusion is supported by the finding that reduction of nasal carriage by topical treatment with penicillin leads to a significant reduction in the proportion of skin carriers (Moss *et al.* 1948). Though *Staph. aureus* is usually transient in Price's sense, some persons carry this organism so deeply in the recesses of the skin that prolonged sweating is required to bring it to the surface (Devenish and Miles 1939). In such persons it may be regarded as part of the resident flora (see also Gillespie *et al.* 1939, Vierthaler 1940).

In Chapter 66 we have discussed *Str. pyogenes* as an occasional transient member of the skin flora. There is no reason to believe that it ever forms part of the resident flora of the clinically normal skin; and indeed, in the light of Burtenshaw's (p. 142) demonstration of natural fatty antistreptococcal substances in the normal skin, it seems unlikely that it could ever do so.

Among other organisms met with are occasional coliform organisms, *Proteus*, and diphtheroids. Horwood and Minch (1951) were able to isolate coliform organisms from 22 out of 34 food handlers; of the 22 positive samples, *Bact. coli* was present alone or with other members of the group in 13. Diphtheroids are probably located mainly in the sebaceous glands. The healthy skin appears to have some natural self-disinfecting mechanism which is responsible for the rapid disappearance of living organisms implanted upon it (see Chapter 45 and Colebrook and Maxted 1933, Arnold and Bart 1934).

In the skin lining the external auditory meatus, as well as the usual staphylococci, diphtheroid bacilli are not uncommon, and sometimes saprophytic acid-fast bacilli, derived from the cerumen, are met with. In the conjunctival sac, organisms are comparatively scanty, and consist chiefly of diphtheroids, such as *C. xerosis*. The conjunctiva may owe its comparative freedom from bacteria, in part, to a highly potent lytic enzyme, called by Fleming and Allison (1922) *lysozyme*. These workers found that tears have a high bactericidal power, capable of dissolving certain saprophytic cocci in a dilution of 1/40,000. Further study showed that, with the exception of cerebrospinal fluid, sweat, and urine, this enzyme is distributed to a greater or less extent in practically all the human secretions and tissues, as well as in animal and some vegetable tissues.

Testing the bactericidal power against a large non-pathogenic coccus, called by them *M. lysodeikticus*, they found the blood serum active in a dilution of 1/270, nasal mucus and sputum in 1/13,500, and saliva in 1/300. Extracts of tissues made by grinding up 1 gm. of tissue with 20 ml. of saline showed that the liver and the tonsil were active at a dilution of 1/400, the kidney and skin at about 1/100, while cartilage was active

Nutritive Requirements

degrees of complexity The kinds of food materials that must be supplied to an organism may be considered to fall into three categories.

- (1) compounds that can be oxidized by the organism and thereby serve as sources of energy,
- (2) compounds that serve as building stones or as precursors to building stones in the synthesis of bacterial protoplasm, and
- (3) substances which, for want of a better name, are designated as growth accessory substances or vitamin-like substances and which, in many cases, appear to function as components of catalytic systems in the economy of the organism

Although such a classification of food materials is convenient for purposes of exposition, sharp distinctions are sometimes difficult to make, as will appear.

In general, the utilization of a given substance as a food by an organism is dependent upon two factors. One, perhaps the more obvious, is the possession by the organism of enzyme systems which make possible the decomposition or assimilation of the substance in question. Cellulose, for example, is not a food for organisms which are unable to decompose it. The second factor is the concentration of the substance, which may vary from a lower limit below which the bacterium is unable to grow to an upper limit beyond which additional material is simply excess. Very high concentrations may actually be toxic, viz., the preservation of foods in syrups. Butterfield²¹ has shown that between these two limits a regular relation exists between the amount of bacterial growth and the concentration of nutrient material, if the logarithms of the maximum numbers of bacteria are plotted against the logarithms of the concentrations of food, the points fall on a straight line. The maximum numbers of bacteria are, in turn, dependent upon the size of the individual organisms, the relation between size and numbers of individuals being inverse—the smaller the bacterium the greater the number of individual cells. When the volume of cells is taken into consideration, however, it appears that a given volume of bacterial substance is formed in a given concentration of nutrient, the larger numbers of small organisms being but a consequence of wrapping the same amount of protoplasm in smaller packages.

Oxidizable Substances. The compounds that may serve as sources of energy to the growing bacterial culture have already been discussed in connection with the mechanisms of oxidation used by these organisms. Suffice it to say that the autotrophic forms require as food material the inorganic compounds of nitrogen, sulfur and iron that they can oxidize, and that such compounds may be regarded as nutriment in the same way that carbohydrates and amino acids are regarded as foodstuffs for the heterotrophic forms. The autotrophic bacteria, however, exhibit a high degree of specificity with respect to oxidizable substances which has no counterpart in the metabolism of the heterotrophic microorganisms. The latter, both as a group and as individual species, may obtain energy from a great variety of organic compounds of carbon and nitrogen. As long as such compounds are susceptible to attack by the enzyme systems of the bacterium, they may serve as food materials.

"Building Stones." The second group of food substances, those that serve as building stones, may be considered as sources of the chemical ele-

²¹ Butterfield Pub. Health Repts., 1929, 44:2865.

mesenteric glands or the liver; a few may perhaps make their way to the blood stream, from which they will be removed by phagocytic cells. In support of this possibility is the observation that the muscles and viscera of apparently healthy cattle and pigs not infrequently contain bacteria (Zwick and Weichel 1911, Reith 1926). Different animals, however, seem to vary in this respect. Schweinburg and Sylvester (1953), for example, found that the organs of rats, guinea-pigs, and golden hamsters were sterile, but that 80 per cent. of samples of tissues from dogs and 40 per cent. from rabbits yielded clostridia—mainly *Cl. welchii*.

The now common diagnostic practice of sternal puncture also offers a means of exploring the bacterial content of the reticulo-endothelial system in healthy persons. So far, its bacteriological use has been confined to culture of marrow samples as an aid to diagnosis in infections where the blood culture is sterile. A wide field of experimental work is open to the student who is willing to study the distribution of living organisms in the tissues of apparently normal animals.

ments which, in appropriate and often highly complex combinations, make up the bacterial protoplasm. Chief among these elements are carbon and nitrogen which the organism may be able to assimilate in a variety of forms. The heterotrophic microorganisms require organic compounds as sources of carbon but do not appear to be particularly fastidious as to the nature of these compounds as long as they may be attacked by the bacterial enzymes. An organism may, for example, assimilate some of the carbon of a fermentable sugar or it may grow normally in the presence of one or more amino acids in mineral salt solutions. The apparent relative unimportance of the nature of the carbon compound suggests that bacteria may break down all manner of carbon compounds to one or more substances which they use as a starting material for the synthesis of cell substance. The intimate relation between glycolysis and the synthesis of carbohydrate and amino acids has been pointed out earlier. The source of nitrogen is either ammonium salts or ammonia liberated by deamination of amino acids supplied in the medium.

The Essential Elements. Elements other than carbon and nitrogen are a part of the bacterial protoplasm and must, of necessity, be supplied in a culture medium. Oxygen is, of course, contained in carbohydrates and amino acids as well as available in the gaseous form to all but the obligate anaerobes. Of the other elements, phosphorus predominates quantitatively because of the high nucleic acid content of the cells. It is generally supplied in the form of phosphate and probably may be assimilated by the organism in the form of other inorganic compounds. A number of other elements, such as iron, magnesium, calcium, etc., have been shown to be necessary to bacterial growth, and certain organisms may have special requirements as in the case of *Azotobacter*, which requires the presence of elements such as molybdenum and vanadium for nitrogen fixation (which in this case is growth, since the nitrogen is fixed as bacterial protoplasm). It has been found also that iron concentration is of paramount importance in toxin formation by the diphtheria bacillus, the optimum amount being 0.14 micrograms per milliliter.⁸² Similar results have been obtained in studies of the formation of tetanus toxin.⁸³ Iron concentration has also been shown to determine the type of sugar fermentation produced by *Cl. welchii*; with adequate amounts of iron, it is of the acetic acid-butyric acid type with not more than 20 per cent conversion to lactic acid, but with iron deficiency very little volatile acid is formed and 85 per cent of the sugar is converted to lactic acid.⁸⁴ Probably a great number of chemical elements go to make up the bacterial cell substance and are, therefore, necessary parts of the food supply, but in the great majority of cases they are required only in the minute traces with which many chemical compounds of the highest purity are contaminated. Obvious technical difficulties have prevented intensive study, but it is quite likely that all of these "biologically rare" elements may be assimilated in the form of inorganic compounds.

The Essential Amino Acids. Bacteria not only require elements such as carbon and nitrogen, but many require them in the form of preformed molec-

Bacterial Vitamins

ular structures. It has been pointed out that the failure of certain bacteria to grow in mineral salt solutions containing fermentable carbohydrate and ammonia might be accounted for on the assumption that such organisms lacked the ability to synthesize certain molecular structures, such as those contained in certain amino acids, and, in consequence, such structures might have to be supplied preformed. The basic assumption is, of course, analogous to the concept of "essential" amino acids in animal nutrition. A considerable quantity of evidence indicates that a number of bacterial species require the presence of certain amino acids in order to grow in mineral salt solutions. One strain of the diphtheria bacillus, for example, has been found to require a mixture of tryptophane, cystine, methionine, valine, histidine, glycine and glutamic acid, while another requires leucine, methionine, valine and glutamic acid. *Clostridium botulinum* requires cystine, leucine, lysine, glycine and proline, and another anaerobe, *Clostridium sporogenes*, requires tryptophane, cystine, leucine, methionine, valine, tyrosine, histidine, arginine and phenylalanine. The amino acid requirements of streptococci are similarly complex. The requirements of some other organisms are not so elaborate, some strains of the typhoid bacillus, for instance, will grow in a mineral salt solution plus tryptophane, while others need no amino acids. The significance of observations such as these is not altogether clear at the present time. It is assumed, of course, that such required amino acids are directly assimilated as building stones which the organism is incapable of synthesizing as indicated above; but the demonstration of the oxidation reduction of pairs of amino acids by obligate anaerobes indicates that these compounds may sometimes function as energy-yielding compounds rather than building stones. Furthermore, analytical evidence⁶⁶ suggests that the apparent necessity for the inclusion of amino acids in mineral salt solutions may not be indicative of a lack of synthetic abilities on the part of the microorganisms.

The direct assimilation of amino acids by bacteria has been shown by Gale and his associates,⁶⁷ who concluded that an associated fermentation of glucose is necessary for the passage of glutamic acid across the cell membrane, and for the passage of lysine out of the cell. The relation of such assimilation to the amino acid requirements of bacteria is not clear, but it may be noted that here again an intimate relation between glutamic acid and glycolysis is indicated. Indeed, further studies on glutamic acid assimilation have suggested that antibacterial substances such as sulfathiazole, triphenylmethane dyes and surface active compounds interfere either directly or indirectly with its assimilation.⁶⁸ an observation perhaps to be related on the one hand to the activity of glutamine as a bacterial vitamin (see below), and on the other to its possible role in the synthesis of amino acids by transamination reactions.

Growth Accessory Substances or Bacterial Vitamins. The third group of food materials, the growth accessory substances, consists of organic compounds which are necessary to growing bacteria only in minute amounts. Presumably these substances cannot be synthesized by the cell, thereby resem-

CHAPTER 91

THE BACTERIOLOGY OF AIR

IN Chapter 59 we have already discussed the apparently conflicting views of Cornet and of Flugge on the respective parts played by dust and by droplets in the spread of pulmonary tuberculosis. More recently observations in this country and in the United States have focused attention on the part played by aerial infection in the causation of other respiratory diseases. Work is now proceeding actively on aerial microbiology, and particularly on the ways in which spread of infection by dust and droplet nuclei can be controlled. We shall attempt to give a brief résumé of the present position, and refer our readers for a fuller account of the earlier observations to the Symposium on Aerobiology held at Chicago in 1942 (Report 1942), and for more recent reviews and studies to Rosebury's (1947) monograph on experimental air-borne infection, to the report of the Committee on Research and Standards (Report 1947), to the report of the Medical Research Council (Report 1948), and to papers by Williams (1948, 1949a, 1951).

Outdoor Air

The degree of bacterial contamination of the outside air depends on a number of factors, such as the density of the human and animal population, the amount of vegetation, the nature of the ground or soil, the temperature and humidity of the atmosphere, the extent and direction of wind currents, and so on. Aeroplane surveys (see Proctor 1934, 1935, Proctor and Parker 1938) show that bacteria in the upper air consist largely of aerobic spore-bearing bacilli, and to a much less extent of organisms belonging to the *Achromobacter*, *Sarcina*, and *Micrococcus* groups, suggesting that they are derived mainly from soil and surface dust. Their numbers are much the same over land and sea (Pady and Kelly 1953). These organisms can be carried vertically for several miles into the air, and it is possible that they may also travel long distances horizontally. It is conceivable therefore, that certain resistant pathogenic bacteria like the anthrax bacillus, and viruses like the virus of foot-and-mouth disease, might be transmitted from one area or country to another, and serve, on again reaching the ground, as infective agents for man or animals. There is, however, no evidence to prove that this is more than a possibility. On the contrary, most of our observations suggest that infective material is seldom carried for more than short distances by air, or that, if it is, it is too diluted to cause recognizable disease. Though autotrophic bacteria may possibly undergo some multiplication in cloud areas, where moisture and traces of gases such as NH_3 and CO_2 are present, it seems extremely improbable that growth of pathogenic organisms can occur in air. For the medical bacteriologist the importance of the flora of the outside air still remains to be

bling the essential amino acids but differing from them in that the growth accessory substances apparently function in the cell economy as catalysts rather than building stones for cell substance proper. The search for such substances goes back over many years, even antedating the discovery of the vitamins of mammalian physiology. The great majority of investigations were based upon a general type of experiment in which a solution which did not support the growth of the bacterium under consideration was supplemented by extracts of various plant and animal tissues. Since many of these extracts permitted growth in the otherwise inadequate solution, it was assumed that they contained active substances which were variously termed biocatalyzers, growth hormones and the like. The interpretation of experiments carried to this point but no further is exceedingly difficult. In very recent years, however, more precise information regarding these substances has become available.

It is of particular interest that the majority of these substances have proved to be identical with various components of the vitamin B complex, suggesting a close relation between the metabolic processes of organisms as diverse as bacteria on the one hand and mammals and other higher animals on the other. It is not inappropriate, therefore, to refer to these substances as *bacterial vitamins*. Other substances required by bacteria and included in this category are glutamine, purines such as adenine or uracil, pimelic acid, and others. The requirements of a number of bacteria have been worked out in some detail⁸⁹ but it should be noted that there may be, and often is, considerable variation from strain to strain of the same species.

The first bacterium to be studied in detail in this respect was the diphtheria bacillus which Mueller⁹⁰ found to require nicotinic acid and β -alanine, the latter presumably serving as a precursor of pantothenic acid; some strains require pimelic acid. *Staphylococcus aureus* was similarly studied by Knight⁹¹ and found to require nicotinic acid and thiamine and, for anaerobic growth, pyruvic acid and uracil had to be supplied. It has been found by others that certain strains require biotin. Similarly, the lactic acid bacteria have been found to require riboflavin, pantothenic acid, nicotinic acid, pyridoxine and other as yet unidentified substances, and the hemolytic streptococci must be supplied with pantothenic acid, pyridoxine, thiamine, nicotinic acid, glutamine and certain purines.

In other instances precise study has made possible an understanding of growth requirements already known. Thus, in the case of the hemophilic organism, the influenza bacillus, it has long been known that two substances present in fresh blood media are required. One of these, the "X factor," is heat-stable and associated with hemoglobin, while the other, the "V factor," is heat-labile and found in yeast and various vegetable extracts as well as in blood. It is now known that the X factor may be replaced by hematin and the V factor by coenzyme I or II.

Other bacteria, however, have much simpler nutritive requirements. The typhoid bacillus, for example, does not require added growth accessory sub-

fallen to any appreciable extent. On evaporation, they become converted into what Wells calls "*droplet nuclei*," which behave very much like minute particles of smoke. In absolutely still air they fall at the rate of probably 1 to 3 feet per hour, but in the ordinary atmosphere they remain suspended almost indefinitely,

TABLE 182

EVAPORATION TIME OF WATER DROPLETS IN UNSATURATED STILL AIR AT 22° C
(Taken from Jennison 1942, modified from Wells 1934)

2,000	515 0
1,000	129 0
500	32 0
200	5 2
100	1 3
50	0 31
25	0 08
12	0 02

being dependent for their transportation on air currents. It has been shown experimentally that micro-organisms attached to droplet nuclei are rapidly dispersed throughout rooms and even buildings, and are inhaled by anyone breathing air containing them (Wells and Wells 1936).

Trillat (1938) described an interesting experiment in which he atomized one litre of a fluid suspension of *Chromobacterium prodigiosum* in a central court of the Pasteur Institute in Paris. A hundred agar plates were exposed for more than 100 metres around. Every single plate became infected, even those placed to windward of the court.

Droplets are also expelled, though in much smaller numbers, during coughing, as in a sneeze, the vast majority are not projected more than 2 or 3 feet. In talking, particularly in the pronunciation of sharp consonants like p, b, t, f, k and s, droplets are often expelled through the teeth; their average size is larger than of those in a sneeze, but their initial velocity is lower, and few travel more than a foot. (For photographs of droplet expulsion in a sneeze, see Weyrauch and Rzymkowski 1938, Bourdillon and Lidwell 1941, Jennison 1942.)

What proportion of droplets and droplet nuclei contain bacteria, and of these what proportion are infective, probably varies greatly from patient to patient. Duguid (1946a), who held plates 3 inches in front of the mouth of patients during a series of six voluntarily produced coughs, found that 39 out of 87 patients suffering from scarlet fever or carrying hæmolytic streptococci in the throat expelled infected droplets. The number of infected droplets varied with individual patients from 0 to 400. Of all droplets expelled by the 87 patients, only 10 per cent. contained hæmolytic streptococci. Similar observations were made on patients affected with diphtheria and pulmonary tuberculosis.

Droplet nuclei are, of course, much smaller than droplets and hence less often contain bacteria; on the other hand there are far more of them.

From experiments carried out on patients during sneezing and coughing, Duguid (1946b) found that droplets and droplet nuclei ranged from 0.5 to 2,000 μ in diameter, 95 per cent. being between 2 and 100 μ . Of the droplet nuclei proper 97 per cent. were between 0.5 and 12 μ , the commonest being 1-2 μ . Assuming that saliva, which provides most of the

Growth Accessory Substances or Bacterial Vitamins

stances; most strains of dysentery bacilli and *Proteus* require only nicotinic acid. These nutritive requirements are generally believed to be an expression of limitations in the synthetic abilities of the microorganisms. The assumption

B COMPLEX VITAMINS REQUIRED BY VARIOUS SPECIES OF BACTERIA*

* Data from various authors, modified from table of Stokes, Guinness and Foster. Jour. Bact., 1944, 47:293.

being the same as that first postulated for the essential amino acids, viz., the substance in question is an essential metabolite which cannot be synthesized by the microorganism and therefore must be supplied as such. From this point of view there appear to be varying degrees of limitation. For example, the influenza bacillus requires the entire coenzyme molecule but most bacteria

which measured volumes of air were drawn through a funnel and allowed to play on agar plates. One of the simplest and most effective devices for the collection and counting of air-borne bacteria is Bourdillon's slit sampler (Bourdillon *et al.* 1941). In its original form air was sucked through a slit 0.25 mm wide and impinged on the surface of a rotating agar plate immediately beneath. The rate of suction was adjusted to 1 cubic foot of air per minute, and samples of 2-10 cu. ft. were collected depending on the bacterial content of the atmosphere. The improved model of slit sampler (Report 1948) is now used almost exclusively in Great Britain for measuring bacterial contamination of the air.

Instead of arranging for the organisms to impinge on solid surfaces, they may be collected in broth and the bacterial content of the broth determined by plating. An apparatus in which measured volumes of air are bubbled through broth in a flask was described by Wheeler, Foley and Jones (1941) and is sometimes referred to as the bead-bubbler device. Other methods, such as the atomizer-bubbler device and the aeroscope, making use of the same principle, are referred to in a paper by DuBuy, Hollaender and Lackey (1945), who made a comparative study of various sampling devices for air-borne organisms (see also Report 1948). As a rule counts obtained by the impingement method are less than those obtained by bubbler devices, because many of the colonies are derived from groups of bacteria and not from single organisms. Passage through broth tends to disintegrate the bacterial clumps, though to a very variable degree, and to increase the number of units from which colonies may develop. For estimating the particle-size distribution of viable air-borne bacteria the method described by Goldberg (1950) may prove useful.

Ellott (1941) devised an ingenious method for enumerating bacteria in the air, but so far it has never been properly developed.

Its essential features are first, the trapping of suspended particles by drawing the air sample through a water-vapour mist, and second, the condensation of water on any particles left in suspension by cooling the saturated air. This latter principle is derived from the Wilson cloud chamber, in which the path of electrons is made visible by depositing on them water droplets condensed from a saturated atmosphere by a sudden reduction in pressure.

An electrostatic sampler, depending on the deposition of bacteria according to their electrical charge, was described by Luckiesh, Taylor and Holladay (1946).

For estimating the degree of nasopharyngeal pollution of the air, Gordon (1902-03) long ago, in his study of the ventilation of the House of Commons, suggested that *Str. viridans* should be used, in much the same way as *Bact. coli* is used for measuring the excretal pollution of water. This suggestion was revived by American workers (Buchbinder *et al.* 1938, Wells, Wells and Mudd 1939). Williams and Hirsch (1950) found that the best method was to collect the bacteria in a slit sampler on 5 per cent serum agar containing 5 per cent. sucrose, 1/100,000 crystal violet and 1/400,000 potassium tellurite. The growth of most staphylococci and micrococci was inhibited on this medium, *Str. salivarius* formed distinctive mucoid colonies, and other streptococci could be identified by suitable sampling of colonies. *Str. viridans* is also useful for testing the efficacy of bactericidal agents designed to destroy potentially pathogenic micro-organisms in the air. It can be sprayed into a closed room, and the disinfection rate estimated by plate counts on air collected at measured intervals. The sampling of dust for hæmolytic streptococci is described by Williams (1949b).

media, and cultivation of a chromogenic organism in the presence of dilute antiseptics may result in the complete suppression of pigment formation. Similarly, the incubation of *B. prodigiosum* at 37° C. results in cultures which entirely lack the brilliant red color characteristic of the organism. As a rule oxygen is indispensable to pigment production and most chromogenic species yield no trace of pigment when grown under anaerobic conditions. *Spirillum rubrum*, however, which grows well in the presence of oxygen, is said to form its red pigment only in oxygen-free media. In the case of some of the chromogens the presence of certain chemical compounds or elements in the medium is essential to, or greatly favors, pigment production. Thus phosphates and sulfates have been found necessary for the production of pyocyanin by *Ps. pyocyaneus*, and sodium tartrate has been shown to favor the production of pigment by *B. prodigiosum*. Carbohydrate media (potato, rice and wheat starch) often lead to a particularly brilliant chromogenesis.

The bacterial pigments are chemically of diverse nature. Many of the red and yellow pigments are insoluble in water, but soluble in alcohol, ether and chloroform, and appear to be lipochromes, a group of fatty pigments widely distributed throughout the plant and animal kingdoms; others, like the fluorescent pigment, are soluble in water, but not in ether or strong alcohol, and may be related to the anthracyanins. Of the bacterial pigments, the structure of pyocyanin is known; it has been found to be an entirely new type of dye and the first instance of a phenazine derivative occurring in nature. The bacteriochlorin found in the purple and green sulfur bacteria appears to be closely related to chlorophyll *a*.

The relation of many of the bacterial pigments to the physiology of the organisms is uncertain. Bacteriochlorin is, of course, responsible for the photosynthetic activity of the purple and green sulfur bacteria. Cytochromes *a*, *b* and *c* are present in all bacteria except the obligate anaerobes, separately and in various combinations, and presumably function as a part of the respiratory mechanisms operative during aerobic growth. The presence of cytochrome, however, does not impart color to the bacteria. Other pigments such as pyocyanin and phthiocol (a yellow pigment of the tubercle bacillus) are reversibly oxidized and reduced and may function as hydrogen transport systems; there is some evidence that the former may function as an alternative hydrogen transport system to heme systems in azide poisoning.⁹⁷ The majority of bacterial pigments, however, fall into the group of lipochromes or carotinoids, and appear to be physiologically inert.

Toxins. The results of the parenteral inoculation of bacteria free culture filtrates into experimental animals must be interpreted with considerable caution. A great variety of proteins, bacterial and otherwise, yield, on hydrolysis, split products of high molecular weight that are toxic, and the complex amines that may accumulate in the cultures of certain bacteria likewise give rise to marked symptoms, or even death, when injected intravenously. Some bacteria, however, have been shown to form what are called true toxins to distinguish them from the non-specific toxicity of the decomposing material present in the cultures of a variety of bacteria. These toxins diffuse out of the cells and may be found in the culture fluid and are, in consequence, also spoken of as "soluble toxins" or "exotoxins." They are apparently protein in nature, large molecules

⁹⁷ Lichstein and Soule: Jour. Bact., 1944, 47:239.

(1941a), who studied the air flora in canteens and hospital wards over a period of some months, found that the result of oil treatment of wooden floors was to reduce the number of organisms dispersed into the air on sweeping by about 80 per cent. The oil can be applied to wooden or to linoleum floors, but not to rubber, cement, or concrete. A fresh application has to be made every 6 or 8 weeks.

Observations by van den Ende and Spooner (1941), however, showed that, if bacterial contamination of the air in hospital wards was to be adequately controlled, treatment of the floor alone was insufficient. The bedclothes, particularly the blankets, which constituted the source of the dust, had to be treated too. It proved possible to do this by soaking them in 30 per cent. liquid paraffin in "white spirit," followed by removal of the excess in a hydro-extractor (see van den Ende, Edward and Lush 1941). Woollen materials retained about 2.5 per cent. of their weight of oil, and cotton materials about 6.5 per cent.; they were not perceptibly oily to the touch. In this way the heavy contamination of the air that normally accompanies bedmaking was avoided. Further work by van den Ende and Thomas (1941) showed that liquid paraffin in white spirit could be replaced by technical white oil emulsified very finely in water by means of suitable wetting agents, which had the advantage of imparting bactericidal activity to the bedclothes. The use of these oil-in-water emulsions resulted in a 99 per cent. reduction in the number of organisms liberated during bedmaking. (For technique of laundering garments with oil, see Harwood *et al.* 1944, Puck *et al.* 1946, Leslie 1953.) In practice, Wright, Cruickshank and Gunn (1944) found that in order to control streptococcal cross-infection in measles wards it was essential to oil not only the floors but also the bedclothes, sleeping garments, towels and similar articles. When this was done, a substantial reduction in the cross-infection rate and in the middle-ear complication rate was effected. The experience, however, of most other workers in wards and barracks has not been so encouraging. There is general agreement that the thorough oiling of floors and bedclothes lowers both the general and the hæmolytic streptococcal content of the air considerably, but that it has little effect in diminishing the respiratory or the wound cross-infection rate (Report 1946, Begg *et al.* 1947, Shechmeister and Greenspan 1947, Rountree 1947). The conclusion has in fact been drawn that epidemic respiratory disease is spread more by droplets and droplet nuclei than by dust, though further observations will be required before this can be accepted.

Handkerchiefs are often heavily contaminated with bacteria. Dumbell, Lovelock and Lowbury (1948) found that by gentle shaking about 15,000 particles could be liberated into the air. As the average diameter of these particles was $20\ \mu$, they were able to contain many bacteria. What part the handkerchief plays in the spread of infection is difficult to determine, but investigations in progress with the use of medicated handkerchiefs do not suggest that it is great.

Droplet-borne Infection.—It is clear that no method of chemical disinfection of the air can control droplet-borne infection. Even good ventilation cannot prevent the direct passage of droplets from one person to another. Mechanical means alone, such as face masks worn either by the patient or by the exposed persons or by both, afford hope of interfering with the direct exchange of the respiratory flora. As demonstrated by actual photographs, masks made of fabric alone are not completely impermeable to the droplets expelled during sneezing;

Bacterial Activity in Mixed Cultures

which are synthesized by the organisms capable of forming them, and they have many properties in common with enzymes. The ability to form toxins is one that is possessed by relatively few bacteria, the best known being diphtheria and tetanus bacilli, the botulinus bacillus and the organism of symptomatic anthrax. These substances are, by a wide margin, the most potent poisons known. There is no explanation for this pronounced toxicity, for the soluble toxins do not differ obviously from other plant and animal proteins. Some of the pathogenic bacteria synthesize other substances termed hemolysins which bring about the dissolution of red blood cells. These substances also appear to be proteins. The cell substance of some bacteria, such as the cholera vibrio, some of the dysentery bacilli and others, is toxic upon injection presumably because of the presence of intracellular or endotoxins. The endotoxins differ in a number of ways from the true toxins, and there is some question as to whether they represent toxic substances synthesized by the bacteria or whether the toxicity of the bacterial cells is a result of the decomposition of bacterial toxins is discussed at length elsewhere (Chapter 8).

The Physical Effects of Bacterial Growth. Both heat and light may be generated by bacterial growth. It has been pointed out earlier that bacteria use only a portion of the energy made available by the oxidation of organic compounds, the remainder being liberated as heat. When circumstances are such that the heat cannot escape as fast as it is generated, the temperature of the bacterial environment rises. The rise may be considerable, the heating of manure piles and damp hay in which bacterial decomposition is proceeding actively may bring them to temperatures as high as 70° to 75° C. Under such conditions the thermophilic bacteria become active and maintain these high temperatures. It has been suggested that spontaneous combustion may result from bacterial activity, but this seems improbable.

The phosphorescence sometimes observed upon decaying fish and meat is found most commonly, though by no means exclusively, in sea water and upon the bodies of marine animals, and a considerable number of species have been described. Sodium chloride and magnesium chloride favor the growth of the phosphorescent bacteria, and one or the other of these salts is essential to the production of light. Luminescence is apparent only in the presence of oxygen, broth cultures from which dissolved oxygen has been exhausted by the respiratory activity of the organisms may be made to glow by shaking. Bio luminescence in certain crustacea, such as Cypodina, results from the oxidation of a substance, luciferin, by molecular oxygen in the presence of an enzyme, luciferase. Presumably a similar mechanism accounts for the production of light by the luminous bacteria, but neither luciferin nor luciferase has been isolated from these organisms.²²

BACTERIAL ACTIVITY IN MIXED CULTURES (BACTERIAL ASSOCIATION)

Although the relatively precise knowledge which has made possible the development of bacteriology as a science has been gained through the study of bacteria in pure culture, it must not be forgotten that in nature a pure

in contrast to chemical air disinfectants, ultraviolet radiation is most effective at low relative humidities (Report 1948).

2. *Disinfectant Sprays and Vapours.*—In the early days of antiseptic surgery Lister introduced a carbolic spray to sterilize the air over the wound. It is doubtful how far it was effective. Hewlett (1939), for example, found that to kill typhoid bacilli on paper slips, it was necessary to vaporize 35 gm. of phenol per 1,000 cu. ft. of air, and even then an hour's exposure had to be allowed. It is probable that, had the bacilli been atomized, a lower concentration of phenol for a shorter time would have proved effective; but since more powerful germicides than phenol are now known, the interest of the carbolic spray is mainly historical.

Though sulphurous acid and formalin vapours were used for terminal disinfection in isolation hospitals and sick-rooms, little progress in the destruction of bacteria in the air of occupied rooms appears to have been made till Douglas, Hill and Smith (1928) showed that it was possible to bring about the rapid death of *Bact. coli* in the atmosphere by means of a sodium hypochlorite solution sprayed into the air in very high dilution. In spite of this impressive result, no general interest in the possibilities of aerial disinfection was aroused till the publication of Wells's papers in 1934 and 1936 on the nature and significance of air-borne bacteria in the causation of respiratory disease. In 1938 appeared Trillat's paper on bacterial aerosols, and Masterman's paper on the purification of the air of inhabited rooms by a hypochlorite spray. Since then, intensive study has been devoted by several workers to the problem of finding a suitable chemical agent for disinfection of the atmosphere. Some of the more promising substances may be referred to here.

(a) *Sodium hypochlorite* Masterman (1938, 1941) found that a reduction of over 99 per cent in the bacterial content of the atmosphere could be brought about by atomizing 1 gm. of a 1 per cent. sodium hypochlorite solution in 40,000,000 ml. of air. Evidence suggests that, so far as bacteria of nasopharyngeal origin are concerned, such a high percentage reduction could hardly be expected.

Andrewes (1940) states that 5 ml. of a 1 per cent. hypochlorite solution were required to kill rapidly 95 per cent. of streptococci suspended in the air of a room of about 1,000 cu. ft. capacity; this gives a concentration of only 1 in 5.7 million. Pulvertaft (1944) made similar observations. Bourdillon, Lidwell and Lovelock (1942) found that 2.1 ml. of 1 per cent. sodium hypochlorite solution per 1,000 cu. ft., i.e. 1 in 13.5 million, killed almost all the bacteria projected into the air by sneezing in 3 to 4 minutes. Challinor (1943) observed a reduction of about 33 per cent. of the aerial bacteria, as measured by the slit sampler, after spraying a room with 1 per cent. hypochlorite solution in the proportion of 11 ml. to 1,000 cu. ft., i.e. a concentration of only 1 in 2.6 million. Edward and Lidwell (1943), using hypochlorous acid gas, found it necessary to use an initial concentration of 1 in 800,000 to destroy 90 per cent. of the bacteria. Nevertheless, it is clear that sodium action on most non-sporing pathogenic bacteria.

The effective concentration of sodium hypochlorite is influenced by a number of factors. A low relative humidity and a high content of organic matter in the air are both unfavourable. So also is the presence of phenol vapour. HOCl attacks metal, and is decomposed by organic matter, so that it should not be used, nor should the solution be used on rubber or wool. Hypochlorite sprays are voided in certain electrical equipment, such as transformers.

culture is the exception rather than the rule. Actively decomposing organic matter, for example, contains a great number of bacterial species, and a diseased animal may, and usually does, harbor a variety of microorganisms. The responsibility for a given phenomenon has, in many cases, been fixed upon but one kind of bacterium present in the naturally occurring mixture, the remainder having no apparent significance. The great majority of infectious diseases are phenomena of this type, and it is possible, therefore, to speak of a given bacterium as the causal or etiologic agent of such a disease. Similarly, one microorganism may be shown to be responsible for one kind of fermentation while another takes place as the result of the activity of a quite different bacterium. Modern bacteriology clearly rests upon the generalization that may be made from these facts, the concept of specific microbial etiology. But is this the whole story? It may be asked, first, whether the microorganisms present in a mixed culture are passive with respect to one another or whether one species is affected, either adversely or favorably, by proximity to other actively metabolizing forms; and, second, whether or not a given phenomenon for which no single species can be shown to be responsible may result from the combined activities of a heterogeneous group of bacteria.

Beneficial Associations. With regard to the first of these questions, bacteria have been found to exhibit the various degrees of relationship known to exist among the higher forms of life. Examples of *symbiosis*, a relation in which there is mutual benefit, are rare among the bacteria, but *metabiosis* or *commensalism*, in which one member benefits while the other is unaffected, is commonly observed. Perhaps the most obvious example is the growth of an obligate anaerobe in mixed culture with an aerobic organism. The latter uses up the oxygen in the immediate vicinity, thereby allowing the anaerobe to develop. Sporulating anaerobes are sometimes carried in culture with a non-spore-forming aerobe, for subsequent separation by heat is readily accomplished. In the breakdown of cellulose in the soil, the preliminary hydrolysis by the cellulose-decomposing bacteria yields glucose which may be utilized by a variety of organisms present which are unable to bring about the initial hydrolysis. Similarly, the hydrolysis of protein material by proteolytic bacteria liberates amino acids which may be further decomposed by non-proteolytic forms.

Bacterial Antagonisms.⁹⁹ Bacterial antagonism or antibiosis is also of common occurrence. Fermentative and proteolytic types of bacteria generally do not prosper equally well in mixed culture. As pointed out previously, the bacterial proteases are for the most part tryptic in nature and work best in alkaline environments. The acid reaction resulting from the fermentation of carbohydrate is distinctly inhibitory to these organisms, a fact which has been the basis of attempts to replace the proteolytic flora of the large intestine with an aciduric flora consisting of organisms such as *Lactobacillus acidophilus*. The formation of ptomaines or complex amines, whose absorption presumably leads to "autointoxication," by the proteolytic organisms is thereby suppressed or prevented. Numerous other examples of bacterial antagonism have been reported, many of them apparently somewhat more specific than acid inhibition. The well known overgrowth of the diphtheria bacillus by *Staphylococcus*

⁹⁹ Waksman *Microbial Antagonisms and Antibiotic Substances*. Commonwealth Fund, New York. Revised edition, 1947.

from these findings. Observations carried out in dormitories of barracks for naval recruits over a period of 6 months showed that saturation of the air with triethylene glycol, though greatly reducing the number of air-borne bacteria, was ineffective in preventing influenzal, streptococcal or other acute respiratory infections (Report 1952). Experience of the use of this substance in infants' wards at the Johns Hopkins Hospital was likewise disappointing (Loosli *et al.* 1947).

(d) *Other Substances*.—Lovell, Lidwell and Raymond (1944) suggested the use of *hydroxy-acids* as aerial disinfectants, and claimed considerable success for lactic acid. This substance can be vaporized by dropping a solution on to a hot plate, and the vapour proves bactericidal in a concentration of 3.5 mgm. per cubic metre. *Ozone* in concentrations tolerable by the human respiratory tract has little or no bactericidal activity under practical conditions (Elford and van den Ende 1942, Ingram and Haines 1949). *Balsamic smokes* were investigated by Twort and Baker (1910). They noted that smoke given off by smouldering cardboard, tobacco, and incense was germicidal. Incense was the most effective; 1 part in 160 million of air destroyed salivary organisms within 15 minutes.

The mode of action of the vaporized disinfectants is subject to controversy. According to Trillat (1938), Pulvertaft and Walker (1939), and Twort and his colleagues (1940), atomized disinfectants exert their action in the form of minute droplets—hence the term aerosol coined by Trillat—which come into contact with the suspended bacteria. Other workers maintain, on the contrary, that they act as simple gaseous disinfectants. Masterman (1941), for example, points out that minute droplets of the size postulated by Twort, namely $0.4\text{--}1.0\ \mu$ in diameter, would evaporate in a fraction of a second (see p. 2273), and would therefore no longer be in the aerosol or mist form. He brought evidence to suggest that the disinfectant action of sodium hypochlorite was due to gaseous hypochlorous acid set free by the carbon dioxide in the air. Similarly there is reason to believe that propylene glycol acts essentially in the gaseous form. Vaporization of this substance by heat is just as effective as spraying it in the form of a mist (see Robertson, Bigg, Puck, Miller and Baker 1942). Moreover, calculation shows that the maximum number of contacts possible between the disinfectant and the bacterial droplets is insufficient to account for the extreme rapidity of sterilization so long as the disinfectant is present in the form of an aerosol. If, however, the aerosol droplets are assumed to evaporate almost at once, then sufficient molecules of gas will be liberated within 2 or 3 seconds to produce a lethal concentration of propylene glycol in the bacteria-containing droplets. This explanation is also in accord with the observation that, in the form of a liquid, propylene glycol has a very low bactericidal action, whereas in vaporized form it is among the most active disinfectants known (see also Puck 1947). The term aerosol is somewhat misleading and should probably be reserved for minute droplets of oily substances that do not evaporate in the atmosphere. For a discussion of the theoretical considerations underlying aerial disinfection, the reader is referred to papers by Puck (1947) and Nash (1951) and Report (1948).

It may be mentioned that both to ultraviolet light and to disinfectant vapours Gram-negative bacilli are more susceptible than Gram-positive cocci; that organisms of whatever nature are harder to kill when dried on to particles of dust than when present in the form of droplet nuclei; and that a varying proportion

The Antibiotic Substances.¹⁰² Investigation of antagonistic micro organisms has shown that in many instances the antagonistic effect is due to the activity of a substance formed by the antagonist which is toxic for the affected bacterium. These substances have been termed *antibiotic substances* or *antibiotics* by Waksman. Such substances have been known for many years, the first, pyocyanin, having been isolated by extraction of "blue pus" in 1860 before the causative bacterium, *Pseudomonas pyocyaneus*, was discovered. Many others are now known. In general they are more effective on gram-positive bacteria, and differ from one another with respect to their relative toxicity for various species of bacteria. Their chemical properties indicate that they are of diverse nature, including polypeptides, sulfur-containing compounds, lipids, pigments, quinones and organic bases. Some have been prepared in crystalline form and in a few cases the structure is known. These substances have become of greatly increased interest in recent years since it has been found that, while some are highly toxic to man, others are effective chemotherapeutic agents.

Antibiotic Substances from Bacteria. PYOCYANIN AND PYOCYANASE. The best known antibiotic substances of bacterial origin are those produced by *Pseudomonas pyocyaneus* and by aerobic sporulating bacteria of the genus *Bacillus*. *Ps. pyocyaneus* forms two substances having antibiotic activity, the chloroform-soluble phenazine compound *pyocyanin*, and a substance known as *pyocyanase*, which appears to be a lipid, whose activity is associated with the presence of unsaturated fatty acids in the molecule. A third substance which also shows activity may be isolated by ether extraction; this is a yellow pigment, *hemipyocyanin*, and a derivative of pyocyanin. These substances are all relatively toxic to higher animals.

TYROTHRINICIN. An alcohol-soluble, water-insoluble polypeptide having antibiotic activity, which he named tyrothricin, was isolated by Dubos¹⁰³ from a gram-positive aerobic sporulating bacterium, *Bacillus brevis*. Further investigation made possible its separation into two components, *gramicidin* and *tyrocidin*, of somewhat different properties though both contain "unnatural" amino acids of the *d* series. Gramicidin is a large cyclopeptide containing relatively large amounts of tryptophane and is effective only on gram-positive bacteria. A very similar substance, *gramicidin S*, is formed by a thermophilic variety of *B. brevis* which differs in that it has considerable activity against gram-negative bacteria and is a cyclopeptide hydrochloride with one free amino group, no free carboxyl and one hydrochloride residue, made up of one residue each of *l*-ornithine, *l*-proline, *l*-valine, *l*-leucine and *d*-phenylalanine. Tyrocidin is active against both gram-positive and gram-negative bacteria *in vitro*, but its activity is almost completely inhibited by serum proteins. These antibiotics are surface-active substances and their antibacterial activity is perhaps attributable to their destructive effect on the cell wall of the bacterium.

BACILLUS SUBTILIS ANTIBIOTICS. A number of antibiotic substances have been isolated from strains of *B. subtilis* which vary somewhat in their properties and antibiotic activity, though all appear to be polypeptide in nature. *Subtilin* is effective chiefly on gram-positive bacteria and certain of the acid-fast

The Antibiotic Substances

Bacilli It has low toxicity and is effective in the therapy of experimental infection of mice with pneumococci and guinea pigs with anthrax, and may prove to be an effective chemotherapeutic drug. *Bacitracin* is similar to subtilin and effective on gram-positive bacteria. It is somewhat toxic but non-irritating to tissue and has possibilities as a chemotherapeutic agent. *Bacillin* is highly active on both gram-positive and gram-negative bacteria *in vitro* and is only moderately toxic, but, like tyrocidin, its activity is destroyed by blood and it is completely ineffective as a chemotherapeutic agent. *Eumycin* does not affect gram-negative bacteria but has *in vitro* activity against the diphtheria and tubercle bacilli and some of the fungi. Its toxicity is low but its therapeutic efficiency is not known. *Licheniformis* resembles subtilin in its properties and is regarded by some workers as identical with it.

Other antibiotics from bacteria include *colicin* or *colistatin* referred to above, which are formed by coliform bacteria and inhibit gram-negative bacilli such as the dysentery bacilli. Some of the bacterial pigments show antibiotic activity, including *violacein* from *Chromobacter violaceum*, *phthiocol* formed by the tubercle bacillus, and *iodinin* from *Chromobacter iodinum*, discussed later in connection with competitive inhibition. A substance named *diplococcin* has been obtained from milk streptococci which is active against species of *Bacillus*, *Clostridium*, *Lactobacillus* and *Streptococcus* and which has considerable chemotherapeutic activity in experimental streptococcus infections. None of these have been fully studied.

Antibiotic Substances from Actinomycetes A number of antibiotic substances have been isolated from actinomycetes, especially by Waksman and his co-workers. The more important of these may be considered briefly. The first to be isolated were *actinomycin A* and *actinomycin B*, isolated from cultures of *Actinomyces antibioticus*.¹⁰¹ The two substances, soluble in organic solvents, were both prepared in crystalline form, and the former found to be markedly bacteriostatic and weakly bactericidal, while the latter was chiefly bactericidal. Both are highly toxic to higher animals. *Actinomycin A* is a red pigment and appears to be a polycyclic nitrogen compound, it is usually referred to simply as *actinomycin*. The substances *actinomycin* and *actinomycin* *lysosyme* are formed by *A. albus* and *A. violaceus* respectively and differ from other antibiotics in that their action is primarily lytic. The former is a thermolabile protein which is precipitated by alcohol, acetone and ammonium sulfate, and the latter is a water soluble, thermostable substance very similar to egg white *lysozyme* (avidin) but not identical with it.

STREPTOTRICIN This antibiotic was isolated from cultures of *A. lavendulae* by Waksman and his co-workers. It is adsorbed on charcoal and may be eluted with mineral acids. It is thermostable and precipitated from aqueous solution by alcohol. It is an organic base and has been prepared as the crystalline reineckate which contains no methoxy, methyl or hydrolyzable acetyl groups, and little is known of its structure. It is more active on gram-negative than on gram-positive bacteria, is bactericidal as well as bacteriostatic, and has considerable fungistatic and fungicidal activity. It is of very low toxicity and has therapeutic promise but has not been tested extensively.

CHAPTER 92

THE BACTERIOLOGY OF WATER, SHELL-FISH, AND SEWAGE

WATER

Bacterial Flora in Water.

It is convenient to divide the bacteria found in water into three groups:

A. NATURAL WATER BACTERIA.

In this group are included those organisms that are commonly found in waters free from gross pollution. They may be subdivided as follows:

Bacilli.

- | | |
|-----------------|--|
| (1) Fluorescent | { Gelatin liquefied. <i>Ps. fluorescens-liquefaciens</i> . |
| | { Gelatin not liquefied. <i>Ps. fluorescens-non-liquefaciens</i> . |
| (2) Chromogenic | { Red pigment. <i>Chr. prodigiosum</i> , <i>Chr. indicum</i> . |
| | { Orange " <i>Chr. aurescens</i> . |
| | { Yellow " <i>Chr. ochraceum</i> . |
| | { Violet " <i>Chr. violaceum</i> . |

- (3) Non-chromogenic { These organisms belong mainly to the *Achromobacter* group. They are sometimes divided up according to their reactions on gelatin and milk; but they have so far not received sufficient study to render their classification possible. Gram-positive, spore-bearing aerobes, which produce acid and gas in lactose, appear to be not uncommon (Greer 1923, Porter *et al.* 1935). Members of the coli-typhoid group are not natural inhabitants of entirely unpolluted waters.

Cocci.

- (1) Chromogenic. Generally yellow pigment formed.
(2) Non-chromogenic. *M. candicans*, *M. aquatilis*, *M. coronatus*.

Sarcinae.

Chiefly *Sarcina lutea*.

B. SOIL BACTERIA.

These organisms, though not normally inhabitants of water, are frequently washed into it during heavy rains. Most of them belong to the group of aerobic spore-bearing bacilli, such as *B. subtilis*, *B. megaterium*, and *B. mycoides*. Others, such as *Bact. aerogenes* and *Bact. cloacae*, which may be found on grain, plants and decaying vegetation, and which are aerobic non-sporing bacilli. By ch

STREPTOMYCIN. Streptomycin was also isolated by Waksman from *A. griseus*. It is very similar to streptothricin but somewhat more active. It has been investigated more fully than any other antibiotic except penicillin, in part because its low toxicity and high activity gave therapeutic promise, and in part because its action on gram-negative bacteria supplements, so to speak, that of penicillin on gram-positive forms. On hydrolysis it yields a basic compound, streptidine, and a disaccharide, streptobiosamine. The latter consists of N-methyl-l-glucosamine and a sugar, streptose. The structures of streptidine and N-methyl-l-glucosamine have been established, but that of streptose and the points of attachment of the three are as yet uncertain. The accompanying formula is that suggested by Kuehl *et al.*¹⁰⁵ The activity of streptomycin is somewhat less than that of penicillin on a weight basis, is defined as that amount inhibiting

the growth of a test strain of *Bact. coli*, and is assayed in a manner similar to penicillin (see below). There is some tendency to speak of the unit as a microgram, giving the somewhat disconcerting measure of potency of a given preparation as, say, 750 μg . per mg. The mechanism of action of streptomycin is almost completely unknown other than that it is essentially bacteriostatic in therapeutic concentrations. Of the respiratory reactions only the aerobic oxidation of glycerol is inhibited. It is reversibly inactivated by reduction but there is no evidence that it interferes with the functioning of thiol groups in the bacterial cell. It has proven an effective chemotherapeutic agent in certain infections such as tularemia, but must be given in large doses because the bacteria become drug-fast very quickly.¹⁰⁶

Some other antibiotics are formed by actinomycetes. *Proactinomycin*, formed by *Nocardia gardneri*, is similar to penicillin but somewhat more stable and more toxic. It has been found to have chemotherapeutic activity in experimental streptococcus infection of the mouse. *Nocardine* from *Nocardia coeliaca* has some antibiotic activity against the tubercle bacillus, but only small chemotherapeutic activity. An antibiotic very similar to, and thought by some to be identical with, streptomycin, and designated *streptin* is produced by *Actinomyces* sp.

¹⁰⁵ Kuehl, Flynn, Brink and Folgers. *Jour. Amer. Chem. Soc.*, 1946, 68:2679.

¹⁰⁶ See the review of streptomycin therapy by Keefer *et al.*: *Jour. Amer. Med. Assn.*, 1946, 132:70.

the greatest numbers of organisms in rain are found during the dusty months of June, July, August, and September. Montsouris is situated on the outskirts of Paris; in the centre of the city the air was found to contain 6,040 bacteria per cubic metre, and the rain 19,000 bacteria per litre.

TABLE 185

	Bacteria per cubic metre of Air at Montsouris. Average for 10 Years.	Bacteria per litre of Rain Water at Montsouris. Average for 2 Years.
January	160	8,000
February	145	1,320
March	225	2,920
April	310	2,140
May	305	2,440
June	355	5,600
July	465	5,600
August	455	8,300
September	310	5,770
October	190	3,220
November	195	3,250
December	165	4,330
Mean	275	Mean 5,300

In the open country the organisms may not exceed 10 or 20 organisms per litre of rain.

(b) *Snow*.—This tends to be less pure than rain, probably because the snow-flakes have a greater surface on which to collect suspended particles in the atmosphere; and also because their low temperature conduces to the survival of bacteria. In snow situated on the tops of high mountains, where it will be remembered that Pasteur found the air to be practically sterile, there are hardly any organisms.

(c) *Hail*.—Curiously enough, hail contains more bacteria than either rain or snow. Belli (1902) examined hail that fell in Padua during July, 1901, and found no fewer than 140,000 organisms per litre. Examination of the bacteria showed that they belonged to nine different types. During the formation of hail, it seems probable that rapidly ascending currents of air carry the raindrops up into a region of the atmosphere where they are solidified; falling down they are melted, and again swept upwards and frozen. After they have been frozen and thawed a number of times the hailstones are thrown out on the periphery of the storm centre and finally come to earth (Mason 1902). It is suggested that the air currents carry up to the cloud region quantities of dust, which is thus incorporated in the hail. It is difficult to explain otherwise the presence in it of vegetable cells, and of fluorescent and soil bacteria.

(d) *Ice*.—The number of organisms in ice depends on the nature of the water from which the ice is formed. With the exception of the ice of glaciers, it is generally impure. Its low temperature is favourable to the survival of most bacteria; hence the self-purification that occurs in waters on storage occurs hardly at all, or very slowly, in ice. For a short review on the bacteriology of ice, see Jensen (1943).

(e) *Shallow Wells*.—If protected from contamination in the immediate vicinity

The Antibiotic Substances

Antibiotic Substances from Molds PENICILLIN. Of the antibiotic substances produced by molds, penicillin, found in cultures of *Penicillium notatum* and by far the best known. This is largely because it is highly bacteriostatic and almost completely non-toxic for higher animals and has been found to be a highly effective chemotherapeutic agent. It was first found by Fleming in 1929 but its possibilities were not appreciated until the work of Oxford chemists in 1940. Penicillin is readily soluble in water and is extracted from acidified aqueous solution with ether or amyl acetate, and may then be taken out of the organic solvent by shaking with dilute bicarbonate or barium hydroxide solution. It may be purified by chromatographic adsorption and the salts are stable in the dry state.

Very considerable interest has attached to its structure because of its high chemotherapeutic activity. It has been prepared in crystalline form; there is some uncertainty about the structure and the β lactam form shown here is

The β -lactam structure of penicillin

generally regarded somewhat more favorably than the alternative incipient azlactone form.¹⁰⁷ Prior to the elucidation of its structure, it was apparent that penicillin is not a single substance in that the product formed by different strains of *Penicillium* differed. First three fractions, designated F, G, and X in the United States and I, II, and III in Britain, were differentiated, and later a fourth fraction, designated K, was found. The antibiotic produced by *Aspergillus giganteus* is a reduced form of penicillin F, and designated dihydro F, and the antibiotics produced by *Aspergillus flavus* and originally described as flavicidin and flavicin were found to differ from penicillin F only in the position of the double bond in the side chain. With the elucidation of the structure of penicillin it became apparent that these penicillins are derivatives of the parent compound shown here with respect to the R group. Thus, penicillin F is Δ^2 pentenyl penicillin, dihydro F is *n*-amyl penicillin, G is benzyl penicillin, X is *p*-hydroxy benzyl penicillin, and K is *n*-heptyl penicillin. These relationships are summarized in the accompanying table. Of these penicillins, X is the most effective, G and F less so, and K is relatively ineffective, presumably because it is rapidly inactivated in the body.¹⁰⁸

Penicillin is most active on gram positive bacteria but some gram negative forms such as the gonococcus are susceptible to it. It appears to act primarily as a bacteriostatic agent though high concentrations may be bactericidal. In general it is more active than the sulfonamides and less so *in vitro* than the triphenylmethane dyes. Bacteria exposed to penicillin become swollen and fail

¹⁰⁷ See Clarke, Johnson and Robinson: *The Chemistry of Penicillin* Princeton University Press, 1948.

¹⁰⁸ See the discussion by Housewright, Berkman and Henry. *Jour. Immunol.*, 1947, 57, 343.

from that in surface waters; the organisms develop slowly at room temperature, there are few liquefying colonies, and chromogenic organisms are relatively numerous (Prescott and Winslow 1913).

B. Nutrition.—The amount of available food supply is probably the most important factor of all in determining the number of bacteria in a given water. When organic matter is plentiful, organisms abound; when it is scarce they are few, and tend to die out.

C. Temperature.—The effect of temperature varies with the amount of organic matter present. A rise of temperature in a water containing an ample food supply for the bacteria causes them to multiply rapidly; but when the organic matter is small in quantity, a rise in temperature has the reverse effect; this is probably due to early exhaustion of the food supply, and the consequent diminution in rate of multiplication of the bacteria.

A low temperature, independent of the amount of organic matter present, favours the survival, though not the multiplication, of bacteria. Houston (1913) added typhoid bacilli to raw Thames water, and maintained the samples at

TABLE 186
INFLUENCE OF TEMPERATURE. (Houston 1913.)

Degrees.	No. of Bacilli per ml. surviving after weeks.								
	1.	2.	3.	4.	5.	6.	7.	8.	9.
0° C. . .	47,766	980	65	34	3	3	2	1	00

10° C. . .	69	14	3	03	00	—	—	—	—
18° C. . .	39	3	04	00	—	—	—	—	—
27° C. . .	19	0.1	00	—	—	—	—	—	—
37° C. . .	5	00	—	—	—	—	—	—	—

temperatures varying from 0° C. to 37° C. The initial number added was 103,328 per ml. of water. Table 186 shows how much more rapid was the death of the organisms at 37° C. than at freezing-point. Hamilton (1935), who made observations on the Whangpoo river, found that in the short run from Shanghai to Woosung there was a diminution of 16 per cent. in the colon bacteria during the winter months, and of no less than 97–99 per cent. during the summer months.

D. Light.—It has been asserted that the ultraviolet rays of the sun play an effective part in destroying micro-organisms in water. Procaccini (1893) placed drain water, from which the coarser particles had been removed, in glass cylinders 50 cm. deep, and exposed them for 6 hours to the Italian sun in June. A control cylinder was protected from the light (Table 187). The water in the exposed cylinder was practically sterilized; that in the protected cylinder contained rather more organisms than at the start of the experiment.

It would appear that under laboratory conditions the actinic rays of the sun may exert a bactericidal effect. In nature, however, the conditions are altered. One of the main factors hindering the rays is the opacity of the water, which prevents their penetration for more than a short distance. Even in clear water,

STREPTOMYCIN. Streptomycin was also isolated by Waksman from *A. griseus*. It is very similar to streptothricin but somewhat more active. It has been investigated more fully than any other antibiotic except penicillin, in part because its low toxicity and high activity gave therapeutic promise, and in part because its action on gram-negative bacteria supplements, so to speak, that of penicillin on gram-positive forms. On hydrolysis it yields a basic compound, streptidine, and a disaccharide, streptobiosamine. The latter consists of N-methyl-L-glucosamine and a sugar, streptose. The structures of streptidine and N-methyl-L-glucosamine have been established, but that of streptose and the points of attachment of the three are as yet uncertain. The accompanying formula is that suggested by Kuehl *et al.*¹⁰⁵ The activity of streptomycin is somewhat less than that of penicillin on a weight basis, is defined as that amount inhibiting

the growth of a test strain of *Bact. coli*, and is assayed in a manner similar to penicillin (see below). There is some tendency to speak of the unit as a microgram, giving the somewhat disconcerting measure of potency of a given preparation as, say, 750 μ g. per mg. The mechanism of action of streptomycin is almost completely unknown other than that it is essentially bacteriostatic in therapeutic concentrations. Of the respiratory reactions only the aerobic oxidation of glycerol is inhibited. It is reversibly inactivated by reduction but there is no evidence that it interferes with the functioning of thiol groups in the bacterial cell. It has proven an effective chemotherapeutic agent in certain infections such as tularemia, but must be given in large doses because the bacteria become drug-fast very quickly.¹⁰⁶

Some other antibiotics are formed by actinomycetes. *Proactinomycin*, formed by *Nocardia gardneri*, is similar to penicillin but somewhat more stable and more toxic. It has been found to have chemotherapeutic activity in experimental streptococcus infection of the mouse. *Nocardine* from *Nocardia coeliaca* has some antibiotic activity against the tubercle bacillus, but only small chemotherapeutic activity. An antibiotic very similar to, and thought by some to be identical with, streptomycin, and designated *streptin* is produced by *Actinomyces* sp.

¹⁰⁵ Kuehl, Flynn, Brink and Folkers. Jour. Amer. Chem. Soc., 1946, 68:2679.

¹⁰⁶ See the review of streptomycin therapy by Keefer *et al.*: Jour. Amer. Med. Assn., 1946, 132:70.

between the amount of dissolved oxygen in lake water and the bacterial content; but other factors may possibly have obscured the effect.

H. Protozoal Content.—Huntmüller (1905) showed that flagellates contribute notably to the extermination of bacteria in water. River water naturally polluted by bacteria, or suspensions of *Salm. typhi*, could be cleared in 4 days if flagellates—*Bodo saltans* or *Bodo ovatus*—were added (see also Kyriasides 1931). Stokvis and Swellengrebel (1911) demonstrated a similar action by infusoria—*Colpoda cucullus*. The bacterial destruction was preceded by a rise in the number of protozoa in the water, and was probably due to active ingestion, though this was not demonstrated conclusively. Aerobic conditions and a temperature between 10° and 30° C. were essential. König (quoted from Thresh and Beale 1925) found that in 1 ml of water from a well at the Hygienic Institute of Munich 21 million added typhoid bacilli perished in 24 hours. This he attributed to the action of protozoa. In pure water the death-rate in this time was trifling. Increasing attention is being paid to the action of predatory plankton in the self-purification of naturally polluted waters (Butterfield *et al.* 1931, Hoskins 1935). By keeping the bacterial population below the saturation point, it is suggested that the plankton favours the continuous multiplication of bacteria in the water, which results in its turn in a progressive oxidation of organic matter.

I. Rainfall.—The effect of rainfall on the bacterial content of a water is complex. Rain falling after a drought washes large numbers of soil organisms into the water, and hence increases the numbers of bacteria. If the rain continues for some days, fewer organisms may be carried in during the later period of rainfall so that the stream is diluted with water purer than its own; its bacterial content therefore decreases. A pure stream may be contaminated by rain; an impure stream may be benefited by dilution. As a rule, rivers and upland surface waters contain their greatest numbers of bacteria after heavy rainfall. In Lake Windermere Taylor (1910) observed a close association between the periodic fluctuations in bacterial content and the amount of rain that had fallen in the drainage area during the previous week. The effect is ascribable not only to the influx of organisms, but to the addition of nutritive substances, and to the increased oxygenation resulting from the beating effect of the rain upon the surface of the water.

J. Season.—The monthly variation in the bacterial content of waters depends chiefly on the temperature and the rainfall. In this country, the highest counts are generally found in the winter months, when the temperature is low and the rainfall greatest. Rivers show more variation than upland surface waters (Tables 188 and 189). The Thames in winter is swollen by heavy rain, and the quality deteriorates in consequence of the scouring effect over the whole drainage area. In summer many sources of pollution have dried up, and much of the water in the river is virtually stored or filtered water, derived from underground sources of supply; hence the bacterial content falls (Houston 1917). In upland surface waters, a rise in the bacterial content is not infrequent during July and August, the explanation of this is not clear, but it seems not unlikely that it is the result of dust and soil washings carried in by the summer rains (see Table 189).

In countries in which the water supply is augmented by melting snows the bacterial content rises considerably in spring time. Oslo obtains its water supply from a lake about 160 metres above sea level. During most of the year, Schmelck (1888) found that the number of organisms per ml. was 10 to 60, rising

The Antibiotic Substances

Antibiotic Substances from Molds. **PENICILLIN.** Of the antibiotic substances produced by molds, penicillin, found in cultures of *Penicillium notatum* and produced to a lesser extent by certain other penicillia such as *P. chrysogenum*, is by far the best known. This is largely because it is highly bacteriostatic and almost completely non-toxic for higher animals and has been found to be a highly effective chemotherapeutic agent. It was first found by Fleming in 1929 but its possibilities were not appreciated until the work of Oxford chemists in 1940. Penicillin is readily soluble in water and is extracted from acidified aqueous solution with ether or amyl acetate, and may then be taken out of the organic solvent by shaking with dilute bicarbonate or barium hydroxide solution. It may be purified by chromatographic adsorption and the salts are stable in the dry state.

Very considerable interest has attached to its structure because of its high chemotherapeutic activity. It has been prepared in crystalline form, there is some uncertainty about the structure and the β lactam form shown here is

The β -lactam structure of penicillin

generally regarded somewhat more favorably than the alternative incipient azlactone form.¹⁰⁷ Prior to the elucidation of its structure, it was apparent that penicillin is not a single substance in that the product formed by different strains of *Penicillium* differed. First three fractions, designated F, G, and X in the United States and I, II, and III in Britain, were differentiated, and later a fourth fraction, designated K, was found. The antibiotic produced by *Aspergillus giganteus* is a reduced form of penicillin F, and designated dihydro F, and the antibiotics produced by *Aspergillus flavus* and originally described as flavicidin and flavicin were found to differ from penicillin F only in the position of the double bond in the side chain. With the elucidation of the structure of penicillin it became apparent that these penicillins are derivatives of the parent compound shown here with respect to the R group. Thus, penicillin F is Δ^2 pentenyl penicillin, dihydro F is *n*-amyl penicillin, G is benzyl penicillin, X is *p*-hydroxy-benzyl penicillin, and K is *n*-heptyl penicillin. These relationships are summarized in the accompanying table. Of these penicillins, X is the most effective, G and F less so, and K is relatively ineffective, presumably because it is rapidly inactivated in the body.¹⁰⁸ Penicillin is most active on gram positive bacteria but some gram negative forms such as the gonococcus are susceptible to it. It appears to act primarily as a bacteriostatic agent though high concentrations may be bactericidal. In general it is more active than the sulfonamides and less so in vitro than the triphenylmethane dyes. Bacteria exposed to penicillin become swollen and fail

¹⁰⁷ See Clarke, Johnson and Robinson. *The Chemistry of Penicillin*. Princeton University Press, 1948.

prevents the excess distribution of a bad supply on any one day. Even in a river, the water may not be homogeneous; samples taken from one side may be different in their bacterial content from those taken near the other side (see Table 191). In a reservoir, whether natural or artificial, a greater degree of homogeneity is attained. (3) Devitalization: the organisms die in large numbers, probably from lack of food supply, and ingestion by protozoa. Houston added cholera vibrios to raw river water, and found that after 1 week's storage their numbers had been reduced by 99.9 per cent.; after 3 weeks they could not be isolated even from 100 ml. of water. Table 190 shows the effect of storage on the London water.

The reduction occurs not only in pathogenic organisms and *Bact. coli*, but in organisms of all sorts, though not always equally. Houston states that even 1 week's storage would be more efficacious, in reducing the initial numbers of typhoid bacilli or cholera vibrios in a water, than sand filtration. It should be remembered that pathogenic organisms usually survive longer in pure than in impure water, and therefore pollution of purified water in reservoirs and water mains should be guarded against very carefully (E. W. Taylor 1949).

TABLE 190
EFFECT OF STORAGE. 1907-08. AVERAGE RESULTS. (Houston 1913.)
Bacteria per ml.

	Gelatin, 20°-22° C.	Agar, 37° C.	No. of Samples with <i>Bact. coli</i> in 0.01 ml.
River Thames before storage	4,465	280	10 1%
River Thames after 15 days' storage at Chel- sea	208	44	1.1%
Reduction	95.3%	84.3%	89 1%

It is probably owing to storage that lake waters are so much purer than the streams that feed them. Some rivers with a very low gradient may offer conditions suitable for sedimentation.

L. Filtration.—Natural filtration occurs on a large scale, resulting in the accumulation of the underground deposits of water that are tapped by deep wells and main springs. Its efficacy in the removal of bacteria depends on the nature of the soil, and the depth of the strata penetrated. In loose, porous soils a greater depth must be traversed to ensure the same degree of purification that is attained by filtration through a more compact soil. Evidence suggests that, in a soil of moderate density, the greater part of the bacteria are removed in the first 10 or 15 feet. This is the reason why deep well water is so pure.

Artificially, sand filtration is used to remove bacteria from water in order to render it potable. Houston (1913) finds that this process, which in the London water follows storage for 30 days, removes 98 per cent. of the residual bacteria.

M. Other Factors.—It is known that certain rivers have a bactericidal effect on some of the intestinal organisms. Thus Arloing and Sempé (1924) state that the water of the Saône inhibits the growth of *Bact. coli* but not of *Salm. typhi*. The water of the Isère inhibits the growth of *Salm. paratyphi A*, the Rhône *Salm. typhi*; and the sea at Havre *Shigella dysenteriae* (Arloing and Chavanne 1925,

to divide, and it is generally believed that some process or processes of cell division are affected. There is, however, no evidence as yet as to the nature of its action with respect to the physiology of the bacterium. It is inactivated by an enzyme, penicillinase, which is produced by a wide variety of microorganisms.¹⁰⁹ It is a highly effective chemotherapeutic agent, especially in staphylococcus and streptococcus infections and certain other diseases such as gonorrhea and syphilis.

Standardization. The antibiotic activity of penicillin is assayed by inhibition of growth of standard strains of staphylococci. Growth may be measured by the turbidity of developing broth cultures, but the most commonly used method is that developed by the Oxford group and makes use of inhibition of

THE NATURALLY OCCURRING PENICILLINS

penicillin K	penicillin IV	<i>P. notatum</i> <i>P. chrysogenum</i>	$\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2^-$

growth on agar media. It consists of the inoculation of an agar plate so that a uniform film of growth will develop; small cylinders of glass or porcelain are set end down on the inoculated surface. One is filled with standard penicillin solution which contains one *Oxford Unit* per milliliter, and the others with varying dilutions of the unknown. After incubation there is a clear zone of growth inhibition around the cylinders, about 24 millimeters in diameter in the case of that containing the standard solution. The *Oxford Unit* is, then, defined as "that amount of penicillin which when dissolved in 1 ml. of water gives the same inhibition (i.e., area) as this standard." An International Unit has now been adopted¹¹⁰ which is defined as the activity of 0.6 microgram of the pure crystalline sodium salt of penicillin II or G, a quantity of which is available as a standard.¹¹¹ This unit closely approximates the *Oxford Unit*.

¹⁰⁹ See the discussion by Woodruff and Foster: *Jour. Bact.*, 1945, 49:7.

¹¹⁰ League of Nations, *Bull. Health Organization*, 1945-46, 12:181.

¹¹¹ The method of assay used by the Food and Drug Administration is given by Hunter and Randall: *Jour. Assn. Offic. Agr. Chem.*, 1944, 27:430.

Public Health Association (1936*b*) in the United States have each described standard methods for its performance, to which reference should be made by those desirous of further knowledge. Great attention has to be paid to the sampling of the water (for details see Report 1939*a*), and to the technical performance of the various procedures involved (for error of these see Wilson *et al.* 1935). For reference to the methods used in France see Buttiaux (1951), in the Argentine see Ferramola (1947), and for general information on the bacteriology of water and water supplies see E. W. Taylor (1949). Changes in the coliform flora of samples stored at different temperatures are considered in Reports (1952, 1953*c*).

Plate Count.—In general, the analysis consists in an enumeration of the organisms or groups of organisms capable of forming colonies on a standard nutrient agar medium incubated aerobically at 20°–22° C. for 3 days or at 37° C. for 2 days. Since not all the organisms in water are viable; since many viable organisms, such as those of the anaerobic and nitrifying groups, do not develop under the particular conditions provided; and since some of the organisms occur in groups which give rise to only a single colony—it is clear that the colony count corresponds not to the total number of organisms or even to the number of viable organisms, but only to the number of bacterial units that are able to multiply under the nutritional, respiratory, and temperature conditions supplied. For this reason it should be reported either as the "number of colonies developing per ml.," or more simply as the "plate count per ml."

Coliform Count.—Besides a general bacterial enumeration, an attempt is made to estimate the number of coliform bacteria in the water, and often to ascertain the proportions of the various types of these organisms. The ideal method of doing this would be a direct plate count on a differential medium. So far, however, no medium has been devised that will distinguish with certainty between coliform and non-coliform organisms, or between the different types of coliform bacilli. Partial success in these respects was claimed by Tonney and Noble (1930, 1931*a, b*, 1932*a, b*) for their ferrocyanide citrate agar medium, by Gehm and Heukelekian (1935) and Olsen (1952) for eosin methylene blue agar, by Littman and Stark (1938) for citrate ricinoleate agar, and by Chapman (1951) for triphenyltetrazolium chloride agar.

The usual technique for estimating coliform bacilli is by the dilution method in a liquid medium, which allows the observation of gas production—an important property serving to distinguish coliform from most non-coliform bacilli. As has already been pointed out (Chapter 4), the dilution method is subject to a big sampling error. The results depend not only on the number of dilutions prepared and on the number of tubes of each dilution inoculated, but also on the number of organisms present in each unit volume of the original water. Hence attempts have been made to devise the most economical method of carrying out the examination consistent with reasonable accuracy (Halvorson and Ziegler 1933*a, b*, Swaroop 1940, 1941). Even greater effort has been expended in endeavouring to convert the results obtained into terms of the probable number of organisms present (see Greenwood and Yule 1917, McCrady 1918, Hoskins 1934, Matuszewski and Supińska 1937, Haldane 1939, Pomeroy 1940, Buchanan-Wollaston 1941). No perfect medium has yet been devised that will enable all coliform organisms to develop and produce gas, while suppressing the growth, or at least the gas formation, of other organisms.

British practice favours MacConkey's bile salt lactose medium, but in the United

The Antibiotic Substances

NOTATIN. A second antibiotic substance produced by *P. notatum* was described independently by British workers as *notatin* and by American workers as *penatin* and *penicillin B*. It differs from penicillin in that it is insoluble in organic solvents and is active only in the presence of glucose. It appears to be a flavoprotein, producing hydrogen peroxide from glucose, and the peroxide is responsible for its antibiotic activity.

In addition to penicillin and notatin, a wide variety of antibiotic substances have been found to be produced by molds. Some of these are:

ASPERGILLIC ACID. This substance is produced by *Aspergillus flavus* and is active against both gram-positive and gram-negative bacteria. It is an amphoteric substance, soluble in alcohol, ether and acetone but not in petroleum ether, and its empirical formula is $C_{12}H_{20}O_2$. It is very toxic for higher animals.

PENICIDIN. This substance is also active against both gram-positive and gram-negative bacteria and is produced by a number of species of *Penicillium*. It is extracted from culture fluid by ether at neutrality and precipitated from ether solution by the addition of petroleum ether as a yellow oil. Little is known of its nature.

PENICILLIC ACID. This substance is responsible for the antibiotic activity of some species of *Penicillium*, notably *P. puberulum* and, in contrast to penicillin, is most effective against gram-negative bacteria. It is water-soluble and has been isolated in colorless crystalline form and found to have the empirical formula $C_8H_{14}O_4$. Two other metabolites of *P. puberulum*, *puberulic acid* and *puberulonic acid*, are also bacteriostatic. The former has been isolated as a colorless, crystalline dibasic acid with the empirical formula $C_8H_6O_6$, and the latter as bright yellow prisms with the formula $C_8H_4O_6$. *Puberulic acid* appears to be a quinonoid and *puberulic acid* the corresponding quinol.

CLAVIFORMIN (CLAVACIN, PATULIN, TERCININ, EXPANSIN). This substance was isolated from *Aspergillus clavatus* and named clavacin, and later from *Penicillium patulum* and called patulin, the two were later found to be identical. The name *tercinin* has been used as a synonym for patulin. It is most active against gram-negative bacteria. It is soluble in ether, chloroform, alcohol and water and has been shown to be anhydro-3-hydroxymethylene-tetrahydro- γ pyrone-2-carboxylic acid. It shows greater bactericidal activity than most of the antibiotic substances.

FUMIGACIN (MILLVOLIC ACID). This substance has been found in cultures of *Aspergillus fumigatus* and is active on gram-positive bacteria. It is soluble in alcohol and sparingly soluble in water and has been isolated in crystalline form.

CITRININ. This substance is formed by *Penicillium citrinum* and acts on both gram positive and gram negative bacteria. It is soluble in water and in alcohol and appears to be an organic base.

FUMIGATIN AND SPINULOSIN. These substances were isolated from cultures of *Aspergillus fumigatus* and *Penicillium spinulosum* respectively. Fumigatin has been found to be 3-hydroxy-4-methoxy-2,5-toluquinone, and spinulosin is 6-hydroxy fumigatin. Fumigatin is the more active substance and is effective against such organisms as *Staphylococcus aureus*, the anthrax bacillus and the cholera vibrio.

citrate is distinctive, in the coliform group, of the intermediate and aerogenes-cloacæ types. By making use of probability tables it is thus possible to obtain within 3 or 4 days a quantitative estimate of the organisms belonging to the coliform, the faecal coli, and the intermediate-aerogenes-cloacæ groups. In this method, though the different types may be present in very unequal proportions in the fermented tubes, transference to selective liquid media will enable growth of even minimal numbers to occur.

The value of the 44° C. MacConkey test for picking out *Bact. coli* of faecal origin has now been abundantly confirmed (see p. 761); though in Madras and Singapore some strains of *aerogenes* type—probably Irregular Type VI (see Wilson *et al.* 1935)—were found capable of producing gas at this temperature (Raghavachari and Iyer 1939a, Boizot 1941). The citrate test is less specific for members of the intermediate-aerogenes-cloacæ group when used for direct inoculation from a fermented 37° C. MacConkey broth culture, owing to the ability of some late-lactose and non-lactose fermenters and even *Bact. coli* to grow in this medium (see Bardsley 1938a, Raven *et al.* 1940, Ferramola 1940). In practice, however, this is not usually a serious drawback, since most false positives in citrate occur with the more polluted waters, which would be condemned in any case on the presumptive coliform or the faecal coli count. The tendency now, however, is to omit the citrate test in routine water analysis and to rely on tests for *Bact. coli* I.

The selective liquid media method was adopted officially by the Ministry of Health (Report 1939a) for the differential coliform test in the bacteriological examination of waters. In the extensive trials during the second world war, it proved to be reliable, and to be economical in both time and medium.

Though C. B. Taylor (1945), working in a particular locality, found that as many as 15 per cent. of *Bact. aerogenes* strains produced gas in MacConkey's medium at 44° C., the specificity of the 44° C. MacConkey test for *Bact. coli* in this country is very high. Occasionally Irregular Type vi, which resembles *Bact. aerogenes*, causes trouble. It is found particularly in jute and hemp, and may multiply under suitable conditions in yarn used for packing joints of water pipes (E. W. Taylor and Whiskin 1945). Again, especially in polluted water that has been chlorinated, *Cl. welchii* may cause confusion. This organism usually forms large quantities of gas at 44° C. but only slight acidity. To overcome the difficulties caused by both these organisms Mackenzie, Taylor and Gilbert (1948) recommend subculturing the presumptive positive 37° C. MacConkey broth tubes into brilliant green bile broth and into peptone water and incubating both at 44° C. overnight. The brilliant green suppresses the growth of *Cl. welchii*, and the negative indole test on the peptone water culture excludes *Bact. coli* I.

Classification of Coliform Organisms in Water.—In Chapter 28 we have discussed the classification of lactose-fermenting coliform bacilli according to the general principles of systematic bacteriology. In water analysis it is of greater advantage to classify these organisms in relation to their habitat, paying particular attention to their excretal or non-excretal origin. Such a classification is given in Table 192.

It will be seen that *Bact. coli* Type I, Irregular Type I, and possibly some of *Bact. coli* Type II (see Bardsley 1938a, Stuart *et al.* 1942) appear to find their natural habitat in the mammalian intestine. It is true that strains belonging to the intermediate-aerogenes-cloacæ (I.A.C.) group are often found in faeces, but as a rule they are present in only very small numbers. Their natural habitat is still unknown (see Taylor 1942a, 1951), but most of the evidence suggests that

CLITOROXIN. This substance is produced by *Gliocladium fibratum* and some species of *Trichoderma* and has also been found admixed with fumigatin in cultures of *A. fumigatus*. It is soluble in chloroform and benzol alcohol and sparingly soluble in water. It has been isolated in crystalline form and found to contain both nitrogen and sulfur and possibly an indol nucleus. It is effective on both gram-positive and gram-negative bacteria but unstable except in acid solution.

CHAETOMIN. This antibiotic is formed by *Chaetomium cochliodes* and occurs for the most part in the mycelium. It is extracted from the mycelium with acetone and from the filtrate with ethyl acetate and purified by shaking with bicarbonate, treatment with petroleum ether, and chromatographic adsorption. It is active against gram-positive bacteria but not against gram-negative bacteria.

Bacterial Synergism.¹¹² Association between bacterial species often affects the organisms in such a way that the ability of the individual species to decompose organic compounds may be modified or extended. This phenomenon, termed bacterial synergism, is sometimes qualified into "antagonistic" and "beneficent" synergism, but since the majority of the changes which indicate the combined work of two or more bacterial species cannot be construed as either favorable or unfavorable to the microorganisms, this distinction is often a difficult one to make. Perhaps the simplest examples of synergism are those in which the enzyme system of one organism supplements that of another. A mixed culture of a streptococcus which ferments lactose to acid without gas, and one of the paratyphoid bacilli which does not ferment this sugar, in lactose broth produces an acid and gas fermentation. Similar results have been obtained with mixed cultures of non-sucrose-fermenting *Bacterium coli* and streptococci fermenting sucrose to acid. In such cases the colon-typoid organisms further oxidize the split products resulting from the decomposition of the disaccharide to gas. Probably similar complementary action is the basis of increased yields of propionic acid in mixed cultures of propionic acid bacteria and lactic acid cocci over that obtained with the propionic acid organism alone. Other decompositions, however, are not so readily explained. Cellulose, for example, is often much more rapidly decomposed by bacteria in mixed culture than it is by component cellulose-decomposing organisms in pure culture.

The course of decomposition may be qualitatively different in mixed culture from that in pure culture. It has been shown, for instance, that the acetone-butyl alcohol fermentation of *Clostridium pectinovorum* is transformed into a lactic acid fermentation by mixed culture with *Bacillus voluntans*. A considerable number of pairs of organisms have been shown to produce gas from carbohydrates in mixed culture when neither alone is able to bring about this change,¹¹³ and similarly, mixed cultures of *Clostridium chauveii* and *Bacillus paralactici* form butyl alcohol from glucose although neither alone could produce this change. This ability of mixed cultures of bacteria to bring about

¹¹² See the review by Burrows: *Synergistic Aspects of Bacterial Populations*. Biol. Symp. 1942, 8:89.

¹¹³ Holman and Meekison; Jour. Inf. Dis., 1926, 39:145.

milk after preliminary heating to 80° C. for 10 minutes to destroy non-sporing organisms, or by use of W. J. Wilson's (1928) glucose sulphite iron agar medium.

Typhoid and paratyphoid bacilli are difficult to demonstrate in water, partly because of technical difficulties, and partly because, unless the contamination of the water is continual, these organisms will have died out by the time suspicion of their presence is aroused. By suitable enrichment and selective media—particularly W. J. Wilson and Blair's (1931) bismuth sulphite brilliant green medium—it is often possible to demonstrate their presence in grossly polluted water, though practically never in water that is only slightly contaminated (Ruys 1940-1). Other organisms of the *Salmonella* group may likewise be found, both in polluted river water and in the intestinal contents of fish living in it (Leiguarda *et al* 1950). The *membrane filter* has been recommended for concentrating pathogenic organisms in water (see Clark *et al*. 1951), but it is doubtful whether it will add to the sensitivity of our present methods (see Broscheit 1953). The same doubt underlies the indirect method proposed by Guelin (1918) of examining the water for bacteriophage to different Vi-phage types of *Salm. typhi*.

In the demonstration of *V. cholerae* advantage may be taken of its rapid growth in alkaline peptone water under aerobic conditions, and of the various differential media available (see Chapters 22 and 63).

Interpretation of the Bacteriological Analysis.—Before attempting to give an opinion on the results of a bacteriological analysis, it is essential to gather particulars of the nature of the water, the method by which it was collected, the time of collection, and the amount of recent rainfall. It is sound practice, though not always possible, for the bacteriologist to make a topographical survey of the gathering ground, so as to ascertain the extent and the kind of pollution to which it is subject. If he is unable to do this personally, he should consult a map on which the source of the water and the immediate environment are indicated. Particular care must be given to the mode of collection of the sample; otherwise contamination, especially with coliform organisms, may disturb the interpretation of the results (for instructions, see Report 1939a).

The whole aim of the bacteriological analysis of water is to find evidence of excretal pollution. Since we can rarely isolate directly specific pathogenic organisms, such as *Salm. typhi*, we resort to estimating first of all the number of living bacteria of all sorts in the water, and secondly the number of living bacteria of intestinal origin. The greater the number of bacteria, the greater, presumably, is the amount of decomposing organic matter. The more bacteria of intestinal origin there are, the more likely are pathogenic species to be amongst them. Our evidence therefore is circumstantial, and is frequently open to doubt in its interpretation.

Unfortunately we cannot lay down absolute standards for all waters; but we can lay down a standard for any one water. This is possible by frequent and regularly repeated examinations, which teach us the range of normal variation. We become acquainted, in fact, with the bacterial character of the water. Any striking deviation from the norm is at once regarded with suspicion. On a water which we examine for the first time and for which we have no absolute standards, it is often difficult to express more than a tentative opinion. A high agar count at 22° C., for example, may be significant or it may not; and though the sanitary survey may assist us on this point, it may not be till several examinations under different conditions have been made that we can offer a definite opinion.

Bacterial Synergism

changes of which none of the component species is capable is of interest in connection with the concept of emergent evolution.

One consequence of bacterial association has been of considerable interest in regard to mixed and secondary infections—the alteration of the virulence of a pathogenic bacterium by association with other microorganisms. This alteration may be either a decrease or an increase in the pathogenic powers of the organism. The mild course of mixed infections of the diphtheria bacillus and Friedlander's bacillus has been referred to above, and in this case decrease in virulence is presumably due to inhibition of toxin formation. It is well known that inoculation with soil containing anthrax spores does not always produce the disease even though pure cultures isolated from the same soil are highly virulent. This apparent decrease in virulence is thought by some to have its explanation in the stimulation of a pathogenic bacterium of the animal by the extraneous bacteria present in the soil. On the other hand, virulence may often be increased by inoculation of a non-pathogenic form, with the bacillus of malignant edema increases the virulence of the latter in mixed culture. The mixture of *Bacterium prodigiosum*, a non-pathogenic form, with the bacillus of experimental animals become fatal. Similarly the virulence of the hemophilic bacteria (Chapter 25) is readily raised by inoculation of the experimental animal with mixed cultures. One of the more interesting examples of the effect of microbial association on virulence is that of swine influenza, in which it has been shown that the disease is produced through the combined action of a bacterium and a filterable virus, neither of which is able to produce the disease by itself. Phenomena such as this suggest that the etiology of bacterial associations and the mechanisms which give rise to the observed results is in an unsatisfactory state. Experimental evidence is fragmentary, not in the sense of paucity of observation—the literature on the subject is a voluminous one—but because of a certain discontinuity which makes generalization difficult if not impossible. The interpretation of experimental results obtained with pure cultures is often difficult, and when mixed cultures of two or more different organisms are used, the difficulties are greatly multiplied. The loose use of terminology (some workers use symbiosis, meta-biosis or commensalism, and synergism synonymously) is no doubt an inevitable consequence of lack of knowledge of many phenomena brought about by bacteria under natural conditions probably lies in the development of knowledge of the association of these organisms with one another. It may be noted in passing that bacteria may live an associative existence with higher animals and plants. Symbiotic nitrogen fixation and the relation of the cellulose-decomposing bacteria to their herbivorous animal hosts are among the more obvious instances. Infectious disease of man is, of course, an example of antibiosis or antagonism.

coli type—is the most delicate index we have of recent excretal pollution. With regard to the importance of the intermediate and aerogenes-cloacæ types (I.A.C.) opinion is divided. There are those who maintain that, because these organisms are found in faeces—though only in small numbers—their presence cannot be neglected. There are those who draw attention to the fact that organisms of the aerogenes type are often present in infected urine (Hill *et al.* 1929, Burke-Gaffney 1933), and may constitute the dominant type of coliform bacilli in human faeces (Parr 1936). There are others who point out that, if recent excretal pollution has occurred, faecal coli will undoubtedly be found too, so that the presence of other types in the absence of faecal coli can generally be ignored.

The interpretation is to some extent affected by the rate at which these different organisms die out after gaining access to water. Here again the available information does not provide us with a clear answer.

The vitality of these organisms in water varies with several factors. Houston (1913) found that storage of water for 15 days reduced the number of *Bact. coli* by 80-90 per cent. Gray (1932) and Burke-Gaffney (1933) bring evidence to show that *Bact. coli* dies out more rapidly than *Bact. aerogenes*. Ruchhoft and his colleagues (1933) find that both organisms disappear at about the same rate. Platt (1935) finds that this rate depends to some extent on the temperature, *Bact. aerogenes* surviving longer than *Bact. coli* at 18°-20° C., but not at 0° C. or 37° C. Raghavachari and Iyer (1939b) suspend their judgment. Hamilton (1935), in China, finds that in the summer months *Bact. aerogenes* may actually multiply in water under favourable conditions.

On the whole, the evidence suggests that organisms of the I.A.C. group tend to be rather more resistant to environmental conditions than faecal coli. Their presence in water, in the absence of faecal coli, may indicate either (1) that non-polluted dust or soil has gained access to the water; or (2) that excretal contamination has occurred at a time sufficiently remote to permit the disappearance of all faecal coli organisms; or (3) that the water is subject to a minor degree of excretal contamination heralded, for some reason which is not yet clear, by the appearance of organisms of the I.A.C. group before true faecal coli; or (4) that a contaminated water has been insufficiently chlorinated; or (5) that the water—and this applies to wells and pumps—is being contaminated from such material as old sacking, leather washers, jute packing, or decaying leaves, in which organisms of the I.A.C. type are actively growing. Which of these explanations is correct, it is usually impossible to say on any one sample of water without further examination.

In this country a high proportion of waters giving a positive presumptive coliform test contain faecal coli (Bardsley 1934, 1938a), and it is therefore often unnecessary to distinguish between the coliform types. In the routine control of water supplies from which coliform bacilli are usually absent, the appearance of these organisms demands immediate attention, and differentiation should be carried out in order to obtain a clue to the probable source of pollution. It is likewise called for when a new supply is under examination, as it is always desirable to learn as much as possible about the flora normally present. In other types of water, differentiation is a matter for individual judgment. Generally speaking, there is little point in determining the nature of the types present in a piped water supply if the presumptive coliform count exceeds about 10 per 100 ml., since even if no faecal coli are found the water will still have to be regarded as probably contaminated. In shallow well waters, however, differentiation may be useful with a coliform count up to about 50 per 100 ml., as the degree of excretal

THE EFFECT OF PHYSICAL AND CHEMICAL AGENTS ON BACTERIA

The separation of the environmental factors, that so profoundly affect the life processes of living cells, into two groups, one designated physical and the other chemical, is undoubtedly artificial in many instances. It is often difficult, if not impossible, to differentiate the physical from the chemical; the lethal effect of a germicidal substance, for example, may be a result of a combination of both physical and chemical activity or its mode of action may lie in the borderland of surface and physical chemistry. Nevertheless, such a separation has a certain reality and is useful for purposes of exposition.

Bacteria, like all other living organisms, consist of protoplasm, a delicately balanced, heterogeneous mixture of various substances in colloidal and true solution. The disturbance of this equilibrium through, for instance, the precipitation of constituent protein, is incompatible with the continuation of the complex phenomena of life, and the cell dies. On the other hand, the environment, when favorable, not only does not destroy this equilibrium but makes possible its continuation through growth and multiplication of the organisms. Bacteria, like other organisms, are creatures of their environment; under favorable conditions they multiply rapidly, and under unfavorable conditions either die or remain dormant in a viable state until another opportunity for growth presents itself. In general, they are much more resistant to unfavorable circumstances than are most higher forms of life. A part of this resistance is, of course, a result of the ability of some bacteria to form spores which are relatively highly resistant, but the vegetative cells are considerably more resistant than are the cells of multicellular organisms.

It is not possible to differentiate sharply between these favorable and unfavorable factors. The congruity of a given environmental factor with the protoplasmic equilibrium that is life, is largely a quantitative rather than a qualitative phenomenon. Although high temperatures destroy bacteria, a certain degree of warmth is essential to their growth. Distilled water is toxic to many microorganisms, yet multiplication takes place only in the presence of adequate amounts of moisture. Even the highly active germicidal chemicals often markedly stimulate the growth of bacteria when present in sufficiently low concentrations.

PHYSICAL AGENTS¹

Temperature Relations. Bacteria as a group will thrive under a relatively wide range of temperature conditions. Some of the more hardy, such as

¹ See the review by Rahn *Bact. Rev.*, 1945, 9 1.

into Class 1; that 80 per cent. should not fall below Class 2; and that the remainder should not fall below Class 3. Chlorinated waters ought uniformly to come into Class 1.

For the student's guidance we give two examples of unpiped and unpurified waters destined for consumption by a small population. Though the deep well and main spring water would be safe for a town supply, the second water we quote would have to be purified before its delivery to a large number of consumers would be justified.

DEEP WELL AND MAIN SPRING WATERS

Plate count, agar 3 days at 22° C.	10-200 per ml.
Plate count, agar 2 days at 37° C.	1-10 per ml.
<i>Bact. coli</i> faecal Type I	Less than 1 per 100 ml.
Faecal streptococci	Less than 1 per 100 ml
<i>Cl. welchii</i>	Less than 1 per 1,000 ml.

SHALLOW WELL, LAND SPRING, AND UPLAND SURFACE WATERS

Plate count, agar 3 days at 22° C.	50-500 per ml.
Plate count, agar 2 days at 37° C.	5-30 per ml.
<i>Bact. coli</i> faecal Type I	Less than 5 per 100 ml.
Faecal streptococci	Less than 5 per 100 ml
<i>Cl. welchii</i>	Less than 5 per 1,000 ml.

A filtered river water should conform to the standard of a good shallow well water. If chlorination has been used in addition, then the coli standard should equal that of a deep well water.

The effect of rainfall on the water should be noted carefully. Speaking generally, the less the water is influenced by this factor the better. Though rain in itself contains few bacteria, it may carry in large numbers of undesirable organisms from the soil. A large increase in the number of organisms, especially if attended by a rise in the coli count, should always be regarded with suspicion.

There is often a tendency for more weight to be placed on the results of the bacteriological examination than is justifiable. If the sanitary survey shows the water to be clearly subject to human excretal pollution, then it is not exaggerating to say that a bacteriological examination is redundant. Even should a reasonably good result be obtained on one sample, there is no doubt that repetition on further samples, taken perhaps after heavy rainfall, will reveal the presence of coliform bacilli in large numbers. Bacteriological examination is a delicate tool suitable for revealing pollution too small in amount or too obscure to be noticeable by the ordinary means of the topographical survey. If the relatively crude method of the survey shows the presence of undoubted contamination, then the delicate methods employed by the bacteriologist are seldom required. It follows that no water exposed to known contamination should ever be reported on favourably by the bacteriologist, regardless of what the laboratory findings may be.

Finally we repeat that judgment on the potability of a water can be given only after a careful weighing of all the evidence available. It must be remembered that the mere absence of evidence indicating faecal pollution does not necessarily indicate that pollution has not taken place. All it does show is that at the time the sample was examined, there was no detectable evidence of pollution. It is partly for this reason that frequent examinations are desirable.

The interpretation of the bacteriological analysis, particularly on a new supply,

Temperature Relations

Bacillus subtilis, will grow throughout the range of 6° to 50° C. Others, such as many of the pathogenic forms, are able to grow over a much narrower range, and some of the more fragile organisms will grow only at body temperature, i.e., 37° C., or very close to this temperature. For all these organisms, however, three temperature limits may be distinguished. There is the minimum or lowest temperature at which a given organism will grow, an optimum or temperature of most luxuriant growth, and a maximum, the highest temperature at which growth can take place. The position of these three points differs greatly among different species of bacteria. In general those organisms whose natural habitat is soil or water have optimum temperatures of 22° to 28° C., while those which, presumably as a result of adaptation to a parasitic mode of existence, cannot survive outside the animal body have an optimum of 37° C.

There are, however, bacteria whose optimum temperatures differ considerably from these. Organisms have been found whose optimum temperatures are from 15° to 20° C., and they have been termed *psychrophiles* or cold-loving organisms. Others having optimum temperatures of 55° to 65° C may be found in the soil and hot springs and are called *thermophiles*. The great majority of bacteria have optimum temperatures which lie between these two extremes and, in this terminology, are designated as *mesophiles*.

The optimum temperature for given species of bacteria is generally considered to be that temperature at which the organisms grow "best." The question arises as to whether "best" refers to the rate of growth or to the maximum population attainable. It has been found¹ that temperatures optimum for growth in terms of rapidity of cell division are not always the same as those optimum for the attainment of maximum numbers of cells per unit volume. A culture grown at a temperature at which cell multiplication is most rapid will not attain as high a peak in numbers as a culture of the same organism growing more slowly at a lower temperature.² Other physiological activities of the cell appear to have optimum temperatures that differ from those which are optimum for multiplication. A given sugar may be fermented to a greater extent, albeit more slowly, when the culture is incubated at a temperature somewhat below that optimum for cell division. Similarly, the anthrax bacillus forms spores most abundantly at 30° to 32° C., while its optimum for vegetative multiplication is 37° C.

The continued growth of bacteria at temperatures somewhat higher than optimum may induce physiological changes of a temporary or permanent character. *Bacterium prodigiosum*, for example, fails to form its characteristic red pigment when incubated at temperatures higher than 30° C., but the change is temporary, for subcultures incubated at lower temperatures form pigment normally regardless of how many transfers have been grown at the higher temperature. The anthrax bacillus, on the other hand, when grown for several transfers at 42° C. loses its ability to form spores and becomes avirulent—a change that appears to be permanent. Incubation or storage of bacterial cultures at temperatures lower than optimum does not result in such qualitative

physiological changes; the metabolic activities of the organisms are slowed down and at temperatures below the minimum for growth the bacteria become dormant.

The mechanisms determining the optimum, minimum and maximum temperatures of bacteria are obscure. In some cases they may be dependent upon other environmental factors. It has been shown, for example, that while many of the thermophilic bacteria are able to grow only at temperatures above 50° C. when in contact with air, they are able under anaerobic conditions to grow at the ordinary incubator temperature (37° C.) or even as low as 34° C. Other studies⁴ indicate that the maximum growth temperatures of bacteria bear a definite relationship to the minimum temperature of destruction of respiratory enzymes.

Fig. 22. The effect of different temperatures of incubation on broth cultures of *Staphylococcus aureus*. (After Graham Smith.)

The rate of bacterial growth and metabolic processes increases, like other chemical reactions, with rise in temperature. The temperature coefficient, i.e., the quantitative effect of temperature changes, is such that these rates are roughly doubled for every ten degree rise in temperature. This effect is observed only over a relatively narrow temperature range, from the minimum to the optimum temperature of the bacterial species under consideration.

The Lethal Effects of Heat. Bacteria are readily killed by heat, and the utilization of heat in one form or another is one of the most convenient means of their destruction. The lethal effects of heat are markedly influenced by the amount of moisture present, and so-called moist heat is a much more effective killing agent than dry heat. The resistance of bacteria to moist heat differs somewhat from species to species, the pathogenic forms being in general somewhat less resistant. The resistance of a given species is influenced by

⁴ Edwards and Rettger. Jour. Bact., 1937, 34:489.

difference in the bacterial quality of the water at the inlet and outlet of the bath (Report 1953*b*). In practice the committee recommended that, in swimming-bath water containing 0.2-0.5 p.p.m. of free chlorine, no sample should contain coliform organisms in 100 ml.; and that in 75 per cent. of the samples the plate count at 37° C. on 1 ml. of water should not exceed 10 colonies and in the remainder it should not exceed 100 colonies.

In natural waters used for bathing, such as rivers, lakes and sea, it is impracticable to lay down any bacteriological standard of purity; but where there is reason to believe that sewage is gaining access to the water a count of *Bact. coli* I exceeding 1000 per 100 ml. may be regarded as indicative of potential risk to the bathers (see Moore 1951).

Water-borne Disease.—The main diseases carried by water are enteric fever, dysentery, and cholera. For a description of these reference should be made to Chapters 63, 69, 70. Occasional outbreaks of Weil's disease, tularæmia, infectious hepatitis, and poliomyelitis are on record, but the evidence supporting their water-borne nature is not always convincing. In this country the incidence of water-borne disease is low compared with some parts of the Continent and with the United States, but is by no means negligible. Between 1911 and 1937 there occurred in England and Wales at least 21 outbreaks of disease conveyed by public water supplies, resulting in 1,237 cases of enteric fever, 2,800 of bacillary dysentery, and 7,139 of gastro-enteritis (Report 1939*b*). In the United States, Gorman and Wolman (1939) were able to collect records of 399 outbreaks during the period 1920 to 1936, affecting 115,615 persons. Among the cases of disease were 12,585 of typhoid fever and 101,603 of diarrhoea. Ehassen and Cummings (1948), who analysed the records in the United States for the years 1938-45 inclusive, found a total of 327 outbreaks affecting 111,320 persons. It may be noted that paratyphoid fevers are seldom water-borne. Franklin and Halliday (1937) report one outbreak of paratyphoid A fever in Canada due to contamination of a well water from a resident who had returned to her home suffering from an undiagnosed disease; and there have been 2 or 3 small outbreaks of paratyphoid B fever in this country (see Report 1942, Page 1942). As is apparent from the records just given, diarrhoea and gastro-enteritis figure prominently in water-borne disease. Their nature and causation are not always clear. Some outbreaks may be due to undetected dysentery bacilli, but there seems little doubt that the access of sewage in considerable amount to a water supply may be followed by gastro-enteritis in the absence of any recognized pathogenic organisms (see Kathe and Königshaus 1932, Report 1936*a*, 1937. Pharris *et al* 1938, Ehassen and Cummings 1948, Ross and Gillespie 1952). I

forms of (lene poisoning following the painting of a storage tank.

Infection of the water may occur at the source, during storage, or during distribution. The prevention of water-borne disease demands scrupulous care and supervision of every part of the system, including the protection of gathering grounds (Report 1948) and the health of operatives closely associated with the water itself (see Report 1939*b*).

The danger of bathing in polluted water is difficult to assess. Cases of typhoid and paratyphoid fever due to this cause are invariably sporadic (see Martin 1947), and other sources cannot always be excluded. Unless contamination is recent and heavy, the risk does not seem to be great. If the maximum already suggested for

The Lethal Effects of Heat

two important factors, the ability of the organisms to form spores and the previous history of the culture. Spores are always much more resistant than vegetative forms. Some species when in the spore stage can withstand the temperature of boiling water for upward of sixteen hours. The vegetative forms of most bacteria, on the other hand, are killed at 55° to 58° C. by ten minutes' exposure in the presence of moisture. In general the heat tolerance of bacteria appears to be directly related to maximum growth temperatures.⁵ The time and temperature of incubation influence, to some extent, the heat resistance of vegetative cells. Actively growing cultures in the logarithmic phase are generally somewhat less resistant than are cells removed from cultures containing maximum numbers of viable organisms. The temperature of incubation appears to affect thermal resistance somewhat, in that cultures grown at and above the optimum temperature are more resistant than cultures grown at sub-optimal temperatures.⁶ Previous treatment of both spores and vegetative cells with sub-lethal doses of ultraviolet light reduces their thermal resistance. However, such changes in resistance are usually of no great magnitude.

Of considerably greater quantitative importance is the pH of the liquid in which the organisms are suspended. Variations from neutrality increase, to a marked degree, the heat resistance of many organisms, especially acidophiles, such as tomatoes, and certain bacteria. Acid foods, which have a neutral reaction. Likewise, instruments are boiled increases the time required for sterilization. time tends to reduce rusting.

The death of an organism from heat is determined not only by the temperature reached but also by the time of exposure. The tubercle bacillus, for example, is killed by thirty minutes' exposure at 58° C., twenty minutes at 59° C. and two minutes at 65° C. One may, therefore, determine the thermal death point of a given bacterium by exposure to varied degrees of heat for a constant time; or, similarly, a thermal death time may be determined by holding the temperature constant and varying the time of exposure. Both are useful, the latter possibly somewhat more so.

The effect of heat seems to be injurious even when bacteria are not killed, since the cells that have been heated appear to require a longer period of germination. Hershey⁷ has shown that exposure to sublethal heat prolongs the latent period preceding cell division without affecting the rate of regeneration of the respiratory function, with no evidence of a period of "recovery" distinct from growth. On the other hand, sublethal heating of bacterial spores often has the effect of accelerating germination.⁸

The application of moist heat to the destruction of bacteria may take several forms. Sterilization by means of steam under pressure is the most efficient of these, because it makes possible temperatures higher than 100° C. in the presence of moisture. At fifteen pounds' pressure, for example, the temperature will be 121.3° C., at twenty pounds, 126.2° C., etc. As a rule, exposure to 120° C. for fifteen minutes suffices for the complete destruction of both vegetative

avoids the danger of using the presumptive coliform test. As Dodgson (1938) showed, the 37° test may be grossly misleading, because organisms of the aerogenes-cloacae type may under favourable conditions multiply enormously in mussels, barnacles, raw sea water, and sterilized tank water. By the Clegg and Sherwood method the following standard of interpretation may be tentatively accepted:

<i>Bact. coli</i> per ml of flesh.	Interpretation
Up to 5	Satisfactory
6-15	Suspicious
16 and over	Unsatisfactory

These categories correspond roughly to those adopted by the Fishmongers' Company based on the examination of 0.2 ml. quantities of fluid from 10 individual shell-fish, namely 80-100 per cent. clean, 70 per cent., and 60 per cent. or less (see Knott 1951)

Just as with water, so in the control of shell-fish a careful topographical survey to exclude possible sources of pollution is desirable. Bacteriological examination must remain as an ancillary method to check the results of the sanitary investigation. Valuable information on the sanitary control of the shell-fish industry will be found in a report (1916a) of the United States Public Health Service.

SEWAGE

In this country crude sewage contains about 10 million organisms per ml. capable of developing on gelatin at 20° C., and from 1 to 5 million per ml. on agar at 37° C. In America the numbers appear to be lower. There is often a considerable rise in the summer months. The organisms making up these numbers are of many different kinds, and vary from one sewage to another. Prominent amongst them are the *Proteus* group, the coliform bacilli, streptococci, anaerobic spore-bearing bacilli, natural water bacteria, and the denitrifying bacilli. *Bact. coli* may number 100,000 per ml., *Streptococcus faecalis* 1,000 to 10,000 per ml., and *Cl. welchii* 100 to 1,000 per ml. Pathogenic organisms of the typhoid, paratyphoid, and food-poisoning groups can often be found in crude sewage by the use of appropriate selective media. The poliomyelitis virus has also been demonstrated in it (Paul and Trask 1911, 1912). Sewage is an excellent source of a large variety of bacteriophages.

The process of purification is accompanied not so much by a diminution in the numbers of organisms, as by a change in the distribution of different organisms. Thus in the septic tank, the anaerobic liquefying bacteria are prominent; on the contact beds the aerobic liquefying and the denitrifying bacteria gain the upper hand. It is evident that enormous numbers of bacteria must perish in the process; by a comparison of the microscopic and the gelatin counts, Winslow (1905) found that the ratio of the total to viable organisms was about 20 to 1 in crude sewage, 40 to 1 in effluent, and 100 to 1 in sand filter effluent.

It will be seen that no striking fall occurs in the number of living organisms in the sand filter stage is reached.

A method of sewage disposal that is now widely used is the Activated Sludge Process. Briefly this consists in treating the sewage with about 15 per cent. of bacterially active liquid sludge, in the presence of an ample supply of atmospheric

tive and spore forms of bacteria, although rarely highly resistant spores may be found that are not killed by this exposure. Boiling, i.e., exposure to 100° C., suffices to kill all vegetative forms of bacteria within a few minutes; but sterilization is not effected, for the spores of many of the saprophytic bacilli are not destroyed by boiling for many hours. Since very few of the pathogenic bacteria form spores, boiling contaminated water for a few minutes renders it safe for drinking purposes and the boiling of surgical instruments generally suffices to kill the vegetative cells of pathogenic bacteria, but not the spores of spore-forming pathogens such as those of the tetanus and gaseous gangrene bacilli.

Temperatures as high as 100° C. are not necessary for the destruction of vegetative forms of bacteria, since most of them are killed at 55 to 58° C. if exposed for ten to thirty minutes. In the preparation of vaccines, suspensions of bacteria are usually heated to 60° C. for thirty minutes to one hour (to allow an adequate margin of safety). The tubercle bacillus, *Brucella abortus* and other pathogenic organisms occurring in milk are killed by the process of pasteurization, i.e., heating to 142° to 145° F. for thirty minutes.

Dry heat is much less effective as a germicide than moist heat. Temperatures of 160° to 170° C. must be maintained for two to three hours in order to ensure complete destruction.

The destructive effect of high temperatures on bacteria is apparently associated with the coagulation of constituent protein. The rate of heat coagulation of protein in solution closely parallels the rate of destruction of bacteria by hot water. Furthermore, the effect of the water content of egg albumin on the temperatures necessary for coagulation is similar to the observed relative efficiency of moist and dry heat in the killing of bacteria.⁹

Cold. Bacteria are much less sensitive to low than to high temperatures. As the minimum temperature of a given species is approached and passed, the metabolic activities of the organism become increasingly slower until a state approaching dormancy is reached. Preservation of bacterial cultures in the refrigerator is a common practice, for the rate of death of most bacteria is greatly reduced at low temperatures.¹⁰ Some mortality results from freezing, it is thought to be due to mechanical grinding coincident with the formation of ice crystals. The evidence for this is, however, not altogether indubitable, and attempts to disrupt bacterial cells by alternate freezing and thawing are not particularly successful. These organisms show a remarkable resistance to extreme cold exposure of organisms like the typhoid and diphtheria bacilli to liquid air (−190° C.) and to liquid hydrogen (−250° C.) does not destroy their vitality. Haines¹¹ has shown that the temperature at which frozen bacteria are stored significantly influences the death rate. When *Bacterium coli* was kept at −20° C. 25 per cent of the organisms were still alive after 163 days, while at −2° C. death occurred rapidly and only 4 per cent were found viable after eleven days. Death under such circumstances may possibly be a

⁹ Egg albumin in aqueous solution is coagulated at 56° C.; with 25 per cent water content at 74–80° C., with 18 per cent water content at 80–90° C.; with 6 per cent water content at 145° C. Anhydrous egg albumin may be heated to 170° C. without coagulation.

¹⁰ Some species of bacteria, however, are particularly sensitive to cold gonococci and meningococci, for example, die out much more rapidly in the refrigerator than in the incubator.

Light and Other Radiations

result of the denaturation of constituent protein. The viability of pathogenic bacteria in ice from contaminated sources is discussed elsewhere (p. 252).

Drying. The vegetative forms of most bacteria are killed by drying in air, although the different species exhibit pronounced differences in their resistance. The tubercle bacillus is one of the more resistant and the cholera vibrio one of the more sensitive to drying. In general, the capsulated organisms are more resistant than the non-capsulated forms. Spores are quite resistant to drying, the spores of the anthrax bacillus, for example, will germinate after remaining in a dry condition for ten years or more. The resistance of the pathogenic forms causing disease of the upper respiratory tract is of particular interest in connection with air-borne infection (p. 231), for the length of time that a droplet remains infective is a result, primarily, of the resistance of the particular micro-organism to drying.

The resistance of a given organism to drying is apparently determined to some extent by the rapidity of the drying process and the temperature at which the organisms are dried and stored. If bacteria are frozen rapidly, as with dry ice and alcohol or one of the glycols, dried from the frozen state (the lyophilic process) and the container or ampoule evacuated and sealed, they remain viable with antigenicity and virulence unimpaired for months and years when stored in the refrigerator.¹² It is preferable that they be suspended in a protein-containing solution such as dilute serum before freezing, in the writer's experience broth cultures frequently do not survive. Even bacteria which are sensitive to both cold and drying may be preserved intact by this method.

Light and Other Radiations.¹³ The biological effects of electromagnetic radiation of wave lengths greater than 3000 Å are slight and such effects as may be produced by short radio waves and the visible spectrum are largely due to heat. Visible light becomes bactericidal, however, with the incorporation of appropriate dyes in the suspending medium—photodynamic sensitization—which promote the absorption of light. The pronounced bactericidal activity of sunlight is due in very large part to its content of ultraviolet light of wave length less than 3000 Å. The wave length 2536 Å shows the highest bactericidal activity and it is perhaps more than coincidence that it is also the wave length at which maximum absorption by nucleic acid compounds occurs. Ultraviolet light is non-ionizing but produces an excitation, i.e., the absorption and dissipation of energy do not result in the ejection of an electron and thus the creation of an ion, but rather raise a constituent electron to a higher stage of energy. In contrast to ionizing radiation, ultraviolet absorption depends on molecular rather than atomic structure, and the excited atoms are distributed at random with no tendency to occur in localized areas. This last probably accounts in part at least for the observation that ultraviolet light is much less effective in killing bacteria than is ionizing radiation.

The ionizing radiations include x-rays, α rays, β rays, γ rays, protons and neutrons. X-radiation is, like ultraviolet light, an electromagnetic radiation but the waves are so short, 0.05 to 10 Å, that there is little or no resemblance in the effects produced. Alpha, β , and γ radiations are emitted by radioactive

substances. Of these, α rays are nuclei of helium atoms and may also be obtained from the cyclotron, β rays and cathode rays are fast-moving electrons, the latter being artificially accelerated; and γ rays are natural x-rays of short wave length. Protons are hydrogen nuclei moving at high speed; they are not emitted by radioactive substances but are obtainable from the cyclotron. Neutrons, also from the cyclotron, do not ionize directly; fast neutrons project hydrogen nuclei already present in the irradiated material as protons, and when a slow neutron is captured by an atomic nucleus, the nucleus emits an α particle, a proton, an electron, or a γ ray, depending on the element. As ionizing radiation passes through a substance it collides with successive atoms, ejecting electrons from them and leaving a trail of ions behind it. The ejected electrons may have sufficient energy to produce additional ionizations as they collide with other atoms, giving rise to clusters of secondary ionization. When these are small they do not add appreciably to the effect of the primary ionization, and the path of the ionizing radiation takes the form of a column of ionization. Occasionally the ejected electron has sufficient energy to travel an appreciable distance and produce a large number of ionizations in a different path; such secondary electrons are called δ rays and may be of considerable importance, especially in irradiation with α rays. The effect of ionizing radiation, then, is the production of columnar zones of intense ionization in the protoplasm of the irradiated cell.

The bactericidal activity of radiation is due to a direct effect on the protoplasm rather than to the production of toxic substances in the surrounding medium. Such an indirect effect, however, may assume importance under some conditions, *i. e.*, when the nutrient medium in which the organisms are to be grown is irradiated as in the irradiation of bacteria inoculated on the surface of an agar medium. Basically, the bactericidal effect is due to chemical changes in the protoplasm but the precise manner in which it is produced is not completely clear. It seems unlikely that it is a result of the toxicity of irradiated protoplasm, for the magnitude of the chemical changes produced by a lethal dose is not great, and it is generally believed that the lethal effect is due to a direct hit of key substances within the cell, *the target theory*, and their destruction by the zone of intense ionization created. The lethal dose of ionizing radiation is directly related to ion density, or number of ions formed, and for *Bact. coli* has been found to range from 4000 r ($r =$ roentgen, a unit of measurement) for β rays to 24,000 r for α rays. This dose of α rays, for example, corresponds to an average of one α particle traversing each $0.06\mu^2$ of cell substance. The lethal effect of the activation produced by ultraviolet is much less per unit of energy absorbed, and about one hundred times as much energy is dissipated in a bacterium killed by ultraviolet light as in a bacterium killed by x-rays. Wyckoff¹⁴ has found that about 4 million quanta are required to kill a colon bacillus with ultraviolet light.

The lethal dose of either ultraviolet light or ionizing radiation is independent of the intensity of the radiation and of the temperature at which irradiation is carried out, and the survival curves are logarithmic. These suggest that the lethal effect is a single unit action by a quantum of ultraviolet

¹⁴ Wyckoff: Jour. Gen. Physiol., 1932, 15:351.

dysentery, or food-poisoning bacilli. The milker constitutes a further source of danger if he is carrying hæmolytic streptococci or diphtheria bacilli in his throat or nose, since these organisms may gain access to the milk *via* the cough spray.

Apart from initial contamination of the milk, imperfect cooling is often responsible for the presence of large numbers of bacteria in any given sample. However carefully milk is produced, sooner or later, provided it is kept at a suitable temperature, it will go sour or putrid as the result of bacterial multiplication. If it is to remain sweet for more than a few hours, all milk should be cooled immediately after production to a temperature of 10° C. or below.

It may be noted that the keeping quality of the milk is determined partly by the degree of initial contamination and partly by the temperature at which it is kept. Milk produced under really cleanly conditions has a considerable bacteriostatic power, and shows little bacterial multiplication for several hours, even when incubated at a favourable temperature. On the other hand, the bacteriostatic effect of milk produced under dirty conditions is very slight, and bacterial multiplication sets in rapidly. For this reason it is much easier to distinguish between a milk produced under sanitary, and one produced under insanitary, conditions if the examination is delayed till the milks have stood at a temperature of 60° F. or so for 12-18 hours. After this time a milk produced under clean conditions will still have a low bacterial count, whereas a milk produced under dirty conditions will contain a large bacterial population.

The production of clean milk is largely a matter of technique, not of structural equipment or refinement. Provided all utensils are sterilized by steam, and the surface of the udder and the milker's hands are cleansed, it is possible to produce milk with a very low bacterial content even under unfavourable conditions. It is, however, not easy to maintain a satisfactory technique day in and day out unless suitable conditions and appliances are provided for the workers.

Types of Bacteria in Milk

The bacteria present in milk from healthy cows may be classified into the following groups:

1. Acid-forming Bacteria.—These organisms ferment the lactose in the milk with the production of acids, mainly lactic acid, which combine with the calcium caseinogenate, liberating free caseinogen; this, being insoluble in water, is precipitated in the form of a smooth, gelatinous curd, which shows little tendency to contract and squeeze out fluid. Lactic streptococci, including *Str. lactis* and *Str. faecalis* (see Chapter 24), are among the commonest members of this group. The closely associated lactobacilli may also be included, though under ordinary conditions they do not appear to proliferate very actively. Staphylococci derived from the udder are not infrequently present in milk, but unlike the lactic streptococci they do not as a rule multiply extensively in raw milk kept at ordinary temperatures. Most of the acid-producing organisms gain access to milk from contaminated utensils, many of them are said to be ultimately of vegetable origin, being found on corn, peas, beans, and cabbage (Stark and Sherman 1935).

2. Gas-forming Bacteria.—These organisms ferment lactose with the production of both acid and gas. They produce a smooth, gelatinous curd, which is often riddled with gas bubbles. The acid produced is largely acetic, which imparts an unpleasant flavour to the milk. Coliform bacilli are among the commonest

Other Physical Agents

light or the zone of intense ionization produced by a single ionizing particle, on a key substance in the bacterial cell. In the light of available evidence, the key system affected appears to be the hereditary or nuclear apparatus. Sublethal irradiation induces changes in bacteria analogous to radiation-induced mutations in higher organisms such as *Drosophila*. X-ray induced mutants of bacteria have been studied by a number of workers¹⁵ and, in fact, as yet it is only among x-ray induced mutants of a single parent strain that the gene recombination referred to elsewhere (p. 184) has been found to occur.

Lethal doses of radiation produce no immediately visible change in bacteria, and they continue to be motile, to metabolize, etc. They are, however, unable to reproduce, cell division does not occur and bizarre forms may develop as a result of continuation of metabolic processes other than some key mechanism of division.¹⁶ The manifestation of the lethal effect at the first cell division following irradiation strongly suggests that some mechanism essential to proliferation has been destroyed, and what would be termed a lethal mutation in higher organisms has been produced.

In general, bacteria are much more resistant to the effects of irradiation than are other organisms, and the lethal dose may be as high as 100,000 r in some instances as compared to approximately 175 r for the guinea pig and perhaps 800 r for the rat. Simple killing, therefore, does not account for the accelerated healing observed following irradiation of certain infectious processes, and the bacterial toxins show only partial inactivation following massive doses of radiation.

Other Physical Agents. *Sonic and supersonic vibrations* apparently destroy vegetative cells upon exposure for sufficient lengths of time. Audible sound waves vibrating at 8900 cycles per second have been found to reduce the numbers of viable organisms in a suspension by 99 per cent in a period of forty to sixty minutes. Ultrasonic waves of 300,000 to 1,000,000 cycles per second have been found to reduce the numbers of viable *Bact. coli* from 70,000,000 to 20,000 per milliliter in fifteen minutes. The destruction is presumably purely mechanical if the effects of rising temperature have been controlled. Many attempts have been made to kill bacteria by passing an electric current through their suspensions. If these organisms could be killed in this manner, the sterilization of fluids such as milk would be a simple matter. It appears, however, that an electric current *per se* has no effect on the organisms, although the generation of heat and the liberation of chlorine (arising from the decomposition of chlorides) incidental to the passage of the current may kill the organisms. At pH's compatible with life, bacteria are negatively charged with respect to water and respond to an electric field by moving to the anode. The migration of these organisms in an electric field is termed *electrophoresis*. Studies on alterations and reversal of charge have shed some light on the mechanism of the agglutination reaction (p. 301). Increased pressures have little or no effect on bacteria unless the

cow vary from animal to animal and from day to day, but they may apparently reach several hundred or even thousand per ml. (see Pullinger 1934). Tubercle bacilli may possibly be excreted in the milk in the absence of any definite disease of the udder (Report 1909), but some degree of tuberculous mastitis can generally be demonstrated, though not always clinically, in cows passing infected milk. Milk must become infected from time to time with tubercle bacilli of human type coughed out by tuberculous farm hands or dairy workers, but their demonstration can practically never be accomplished because of the very small number in which they are present and because of their failure to multiply in milk.

Br. abortus.—This organism is responsible for contagious abortion of cattle, which is probably economically more important in this country than tuberculosis. The udder is frequently infected, even in animals that have not aborted (see Chapter 75), though no lesions can be detected by clinical examination. The bacilli are excreted regularly or intermittently in the milk. Their numbers are usually greatest at the beginning of lactation, when they may reach as many as 200,000 per ml, but in the later stages they diminish and rarely exceed 2,000 per ml. (Stockmayer 1936). The udder may remain infected for years. About 30 per cent. of samples of raw mixed milk offered for human consumption appear to contain this organism.

Streptococci.—Mastitis streptococci are of various types, the most important being *Str. agalactiae* (see Chapter 24). They are excreted in variable numbers in the milk of cows suffering from mastitis. This disease is extremely common, and affects not only the poorer herds, but even herds producing high-grade milk. Pullinger (1935), for example, found that the milk from 10 out of 12 herds producing Certified milk and 12 out of 14 herds producing Grade A tuberculin-tested milk contained mastitis streptococci when examined at intervals over a period of 15 months. Most streptococci causing mastitis are probably non-pathogenic for man, but occasionally *Str. pyogenes* of human origin invades the udder, and is responsible for an outbreak of scarlet fever or septic sore throat in persons consuming the milk (see Bendixen and Minett 1938, Dublin *et al.* 1943). The milk may also be contaminated directly with these organisms from persons who are either suffering from streptococcal throat lesions, or who are carrying these organisms in their throat or nasopharynx (see Henningsen and Ernst 1939). Most outbreaks of milk-borne streptococcal infection appear to result from the former method of infection. Though pathogenic streptococci must often gain access to milk from human cases and carriers, their rate of multiplication in raw milk at ordinary temperatures is usually too slow for them to render the milk sufficiently infective to cause disease (see Pullinger and Kemp 1937).

Staph. aureus.—This organism is a not infrequent cause of mastitis. It is often found in the apparently healthy udder, but in cows suffering from mastitis it may be present in large numbers in the milk. Its public health importance lies in the fact that, under favourable conditions, it may multiply in the milk and give rise to a toxin capable of producing gastro-enteritis in human beings (see p. 1808).

C. diphtheriae.—This organism occasionally finds its way into the milk from the throat or nasopharynx of a human carrier or case of diphtheria. Very occasionally it becomes implanted on ulcers on the cow's teats. Such an occurrence is peculiarly dangerous, since the milk is uniformly infected (for references, see Goldie and Maddock 1943).

pressure is high, 5000 to 6000 atmospheres, and the exposure prolonged. Under such circumstances the organisms may be reduced in numbers. Spores are more resistant; the spores of *B. subtilis*, for example, survive 20,000 atmospheres. On the other hand, animal cells are killed by pressures of 1800 atmospheres. Increased pressures of carbon dioxide show more bactericidal activity, non-spore-forming bacteria being killed after ninety minutes' exposure of 50 atmospheres. Such a germicidal effect may possibly be a result of increased acidity. The sudden release of high carbon dioxide pressures may result in the disruption of the cells of some bacteria; the gram-negative forms are more readily broken up in this manner than are the gram-positive. Sudden release of pressures of other gases does not have this effect.

CHEMICAL AGENTS¹⁷

The general subject of the effect of chemical agents on bacteria is a broad one and might reasonably be considered as including not only the germicidal chemicals but also the foodstuffs used by these organisms. It is more convenient, however, to consider the latter in terms of the effects of bacteria on their environment in Chapter 4 under the general head of bacterial physiology.

A certain terminology has grown up about this subject matter which requires definition. The synonymous terms *bactericidal* and *germicidal*, which have already been used, are adjectives indicating a bacteria-killing power. The term *bacteriostasis*, or the adjective *bacteriostatic*, denotes a somewhat less drastic effect. A bacteriostatic substance is one which does not kill bacteria but acts in a preservative manner by preventing their growth. An *antiseptic* is a substance which has a preservative action, possibly killing a few of the bacteria exposed to it, but in general acting predominantly in inhibitory fashion. The term *disinfectant* is applied to substances having bactericidal activity and denotes something more vigorous than does antiseptic. These terms are obviously relative, for a substance that is bactericidal in a given concentration may be only inhibitory or antiseptic in lower concentrations. Furthermore, the specificity of a certain compound for some kinds of bacteria may result in its having disinfectant action with regard to one species but only antiseptic action on another.

Water. In general, bacterial cells suspended in distilled water do not survive more than a few hours, although spores will survive for many weeks. Death of the organisms results from a variety of factors one or more of which has been operative in most of the reported experiments. Water from a metal still, for example, often contains sufficient traces of metals to be toxic, and water sterilized in soda or "soft" glass contains alkali dissolved from the glass. Water freshly distilled from hard glass is neutral but upon standing absorbs carbon dioxide from the air and becomes acid. The pH markedly influences the survival of bacteria in water, the death rate increasing on either side of pH 6.0, which appears to be optimum for longevity. Other factors, such as the number of bacteria suspended in a given amount of water, dissolved oxygen and accessibility to oxygen, etc., are likewise known to affect the survival of these organisms. The osmotic pressure of distilled water, which

¹⁷ See Wyss Ann. Rev. Microbiol., 1948, 2, 413.

and bacteria may gain access to the milk in considerable quantities without endangering the health of those consuming it. On the other hand, if pathogenic bacteria find their way into the milk from one of the sources quoted above, no matter in how cleanly a manner the milk is produced, it is a potentially dangerous and unsafe milk.

These conclusions are borne out by epidemiological experience, which has shown that several outbreaks of disease have followed the consumption of milk of the highest standard of cleanliness. Without discussing this subject further, we shall probably be wise to regard cleanliness and safety as two entirely separate attributes of milk.

For human consumption it is desirable, of course, that milk should be both clean and safe. Clean milk is more aesthetically desirable, it has a better flavour, and it keeps longer. Moreover, it is not likely to contain any of those toxic substances resulting from undue bacterial proliferation, which have an irritating effect on the gastro-intestinal tract—particularly of infants (see Park and Holt 1903 and Chapter 72). The fewer organisms there are in milk, and the more bacterial proliferation is checked, the less liable is the milk to give rise to digestive disturbance of this type.

From this it will be clear that *no raw milk can ever be regarded as completely safe for human consumption*. The frequency of disease in cattle, the risk of contamination from human and other sources, and the suitability of the milk itself as a medium for bacterial multiplication, combine to render the consumption of raw milk potentially dangerous. The only satisfactory way of eliminating this danger is by pasteurization or some other form of heat treatment.

The Antibacterial Property of Milk.—Numerous observers have shown that the growth rate of organisms is much slower in clean than in dirty milk. In clean milk there is a lag phase of variable duration before multiplication begins, whereas in dirty milk kept at a suitable temperature the organisms start multiplying almost at once. Jones and Simms (1930) brought evidence to show that clean milk contains an inhibitory substance to which they gave the name of *lactenin*.

Lactenin is present in the whey fraction of the milk. It will not pass through a dialysing membrane. It is inactivated by heating to 80° C., but not by pasteurization. It will remain stable for some weeks at 6° C., and is not digested by trypsin. It is irreversibly inactivated by the exclusion of atmospheric oxygen and by sulphur-containing reducing agents such as cysteine, glutathione, and thioglycollic acid. It is particularly active towards Group A streptococci, which are not only inhibited but actually killed by it. The susceptibility of these organisms to lactenin may explain the infrequency of streptococcal milk-borne outbreaks (see Wilson and Rosenblum 1952); though as most of the outbreaks that do occur are attributable to milk coming from an infected udder, and as lactenin is inactive *in vivo* owing to the low Eh of the tissues, this explanation cannot be more than partially true. Electrophoretic experiments show that lactenin contains two fractions, 1 and 2; these can be concentrated and separated from each other (Auclair and Berridge 1953, Auclair 1954).

Bacteriological Grading of Milk

In public health practice it is usual to grade milk bacteriologically partly according to cleanliness and partly according to safety. We may consider briefly the various methods available for these purposes.

leucocytes, or to some other cause. A mere count of the cells present affords little information about the quality of the milk, and it would be unwise to condemn a milk solely on account of an increased cell content. If long-chained streptococci are found in addition, the probability is that the cow is suffering from mastitis. Much more information can be obtained by a differential count, but the real value of this method lies in the help it gives to the veterinarian who is engaged in a study of the individual cow.

(3) **The Breed Smear Method.**—The general technique of this method is to spread 0.01 ml. of the milk over 1 sq. cm. on a glass slide, to fix and de-fat, to stain with methylene blue, to count the number of individual organisms—the Breed “individual” count—or preferably the number of groups of organisms, individual organisms each being regarded as a group—the Breed “clump” count—in a given number of fields, and finally to calculate the number of organisms in 1 ml. of the original milk. The result obtained affords an index of the total *stainable* organisms present, not necessarily of the total organisms. The chief value of this method lies in its rapidity, which enables an opinion to be formed on the bacterial cleanliness of a milk within a few minutes. It is particularly suitable for use in collecting stations to which milk from individual farms is brought before being mixed and sent up to towns in large rail or road tanks. Unsatisfactory milks, which would taint the rest, can be picked out quickly, and returned to the producer. With a little experience, a mere glance over a few fields is sufficient to indicate the general quality of the milk. The Breed Smear method is also of value to the farm inspector in indicating the probable nature of the defect in unsatisfactory milk. Thus the presence of large masses and clumps of bacteria suggests unsterilized milk utensils; the presence of numerous organisms arranged in pairs or small units suggests inadequate cooling; the presence of long-chained streptococci associated with a high leucocyte count indicates mastitis, and so on (see Breed 1929).

(4) **The Keeping Quality Test.**—The milk is kept in a special bottle at a given temperature, such as 60° F. or 70° F., and examined every 8 or 12 hours until it becomes sour or putrid. The fact that the end-point is largely subjective necessarily exposes the result to a big experimental error. Some degree of objectivity can be introduced by means of the *alcohol-precipitation* or the *clot-on-boiling test*.

If 1 ml. of a 68 per cent. solution of ethanol is added to 1 ml. of the milk and the tube is inverted, precipitation of the casein occurs in milks that are near the souring point. The clot-on-boiling test is carried out by heating 2 ml. of milk in a clean test-tube in boiling water for 5 minutes, samples showing no sign of precipitation are regarded as passing the test.

Though the alcohol-precipitation method is slightly more delicate, both these tests give similar results and are in general agreement with the grading of the samples by taste (see Anderson and Wilson 1945, Rowlands *et al.* 1950). The subjective keeping quality test, though useful for special purposes, is manifestly unsuitable for routine grading, but the clot-on-boiling test has a good deal to recommend it (see Rowlands and Hosking 1951). It is really an indirect test for the measurement of acidity, though a small proportion of milks may clot on boiling in the absence of acidity if enzymes of the rennet type are formed in sufficient concentration—“sweet curdling.” The modified methylene blue reduction test carried out at 60° F. is sometimes used as an indirect measure of keeping quality (see Provan, Dudley and Thomas 1936).

son of the bactericidal power of the various metallic salts on the basis of percentage solution is misleading; equimolecular solutions must be used and the ionization constants taken into consideration. The bactericidal activity of the heavy metal salts is a result of the affinity of the cations for protein material; when the constituent protein of a bacterial cell is precipitated as an insoluble proteinate, the cell dies. Other factors appear to be involved also, however. Guest and Salle¹⁸ have observed that inorganic metallic salts which are only slightly bactericidal individually may become markedly active when mixed to produce an oxidation-reduction system.

The *oligodynamic action of metals* is possibly a result of the solution of the metal to form salts. The destruction of bacteria in contact with or in proximity to a piece of metal is the basis of some methods of disinfection of water. Water may be sterilized by allowing it to seep through a layer of silver-coated sand, and water containing colloidal silver in amounts sufficiently small to defy chemical detection, by calculation about 40 gamma per milliliter, is markedly bactericidal. Such colloidal solutions are prepared by sputtering silver electrodes in water—the so-called catadyn process.¹⁹

The other cations are less toxic than mercury and silver, but even sodium and potassium are toxic to bacteria in sufficiently high concentrations (ca. 2 molar). It is of some interest that the arrangement of cations in an order of their toxicity—mercury and silver at one end and sodium and potassium at the other, with others falling in order in between—corresponds closely to the Hofmeister series and the lyotropic series of Freundlich, in which cations are arranged in the order of their effects on physical properties of proteins, such as coagulation, solubility, viscosity, etc. The toxicity of cations as manifested in solutions containing a single salt may often be neutralized by the presence, in the proper proportion, of another cation. This phenomenon, known as the *antagonistic effect of salts*, has led to the concept and preparation of so-called balanced solutions such as Ringer's solution, Locke's solution and others. Salts not only modify or enhance the toxic qualities of other salts but also exert similar effects on disinfectant compounds of widely different constitution. Sodium chloride, for example, markedly enhances the germicidal qualities of phenol for anthrax spores when present in sufficiently high concentrations.

The part which anions play in the growth and destruction of bacteria is less well known. Some, particularly those containing sulfur, carbon, nitrogen or oxygen, may serve as sources of these elements and of energy, but in appropriate concentrations many are toxic for bacteria.

Oxidizing Agents. Other salts, such as potassium permanganate and the sodium and calcium salts of hypochlorous acid (HOCl), show marked bactericidal activity owing to their properties as oxidizing agents. Mol for mol, hypochlorous acid is one of the most powerful germicides known, and its calcium salt (commonly known as bleaching powder) has a wide use in the treatment of private and small municipal water supplies. Hypochlorous acid reacts with organic compounds containing an amide group with the formation of compounds known as chloramines. These compounds show strong disinfectant properties which are apparently associated with the presence of the

¹⁸ Guest and Salle: Proc. Soc. Exp. Biol. Med., 1942, 51:272.

¹⁹ For a discussion see Hoffmann: Arch. f. Hyg. u. Bakt., 1938, 120:147.

(Bardsley 1934); (2) organisms of the *Bact. coli* type in water in this country are very frequently derived from human excretal material, and since human faeces and urine may contain pathogenic bacteria, the presence of any excretal pollution, as indicated by the coliform test, must be regarded as potentially dangerous; and (3) as a rule, coliform organisms do not seem to multiply in water under natural conditions; on the contrary, they tend to die out rather rapidly (Houston 1913). In this country, therefore, the coliform count in water indicates the minimal amount of excretal pollution that has occurred.

When we turn to *milk* we find that (1) a considerable proportion—something like 50–70 per cent.—of raw milks in this country in which coliform bacilli are found contain not the true *Bact. coli* but organisms of the intermediate or aerogenes-cloacæ types. These organisms come mainly, not from faeces and urine, but from soil and grain, and their presence therefore in milk cannot be regarded as an index of excretal pollution; (2) the true *Bact. coli* organisms that are found in milk appear to come either directly from cow-dung and manure, or indirectly from unsterilized milk utensils in which bacterial multiplication has occurred. If they are derived from the latter source, they clearly afford no index of *direct* excretal pollution. If they are derived from the first source, their presence may be considered objectionable on the ground that organisms pathogenic for man are sometimes present in the intestinal canal of the cow. The presence, however, in milk of excretal material of bovine origin must be regarded as very much less dangerous for man than that of human origin. (3) Unlike water, milk affords an admirable medium for the growth of coliform bacilli. If it is kept at a temperature of 50° F. or over, a great increase in their numbers may take place, a rise of several thousand-fold often occurring at 60° F. within 24 hours (see Ayers and Clemmer 1918, Finkelstein 1919, Sherman and Wing 1933). Unless, therefore, the milk has been kept at 40° F. or less, an estimation of the coliform bacilli affords only a very imperfect, and often entirely misleading, index of the extent of the original contamination. With a milk produced and kept under ordinary conditions, it is impossible to tell how many of the coliform bacilli gained access at the time of production, and how many are due to the multiplication of those originally present.

It will thus be seen that none of the three premises on which the scientific application of the coliform test to water in this country is based holds true for milk. Even a differentiation of the coliform group into its constituent types is not likely to help us, since (a) it is impossible to tell how many of the different types were original contaminants and how many have resulted from growth, and (b) organisms of the faecal coli group are not necessarily derived directly from excretal material, but may come from unsterilized milk utensils on which they have been multiplying perhaps for several generations.

The presence of coliform bacilli in small numbers in water or milk is not in itself objectionable; it is merely as an index of the possible accompanying presence of pathogenic organisms that it is of importance. In milk, the coliform test cannot be used as an index of direct excretal pollution, for though it is true that if manure gains access to milk, coliform organisms will probably be found, the reverse conclusion does not hold true. There are so many other sources on the farm for these organisms that their presence in milk cannot be held to justify the conclusion that the milk has necessarily been contaminated with excretal material. The coliform test on milk fails to provide us with that specific qualitative information which it supplies in the case of water, and as a general method of grading, therefore, it seems

peculiarly fitted to gauge the keeping quality of the milk. The plate count yields a *static* picture of the bacterial population: the methylene blue reduction test affords a *dynamic* picture. (For comparison between the two tests see Wilson *et al.* 1935, Nichols and Edwards 1936, Asdrubali 1939, Barkworth, Irwin and Mattick 1941, Pullinger 1945, 1946, Provan and Rowlands 1949, Galesloot 1949, Rowlands *et al.* 1950, Johns 1952.)

(8) **The Resazurin Test.**—The principle of this test, which owes its practical introduction mainly to the work of Ramsdell, Johnson and Evans (1935), is the same as that of the methylene blue test. The test consists essentially in adding to the milk a solution of resazurin to give a final concentration of 1/200,000, incubating at a given temperature, and observing the time taken to bring about a change in the colour of the dye, or alternatively noting the colour reached after a given time. The colour passes from blue, through various shades of purple and mauve, to pink, and ultimately to complete decolorization. The change from blue to pink is due to the irreversible reduction of resazurin to resorufin: the change from pink to colourless is due to the reversible reduction of resorufin to hydroresorufin. The colour can be assessed by a suitable comparator. Numerous methods of performing this test have been described (see Johns and Howson 1940, Davis, Newland and Knuckey 1943). In this country a 10-minute test is used for the control of "platform" milk, that is producers' milk arriving at a creamery, in order to see whether it is clean enough to be bulked with other milk. A longer test is employed by agricultural bacteriologists for the control of the general quality of milk at the time of production.

The advantages of the resazurin over the methylene blue test are mainly two. Firstly, resazurin changes in colour rather more rapidly, and though complete reduction takes as long as or even longer than methylene blue, useful information can be obtained by noting a change in colour from blue to lilac or pink. Secondly, resazurin is more sensitive to the cell content of milk, and is therefore regarded by some workers as of value in the detection of mastitis. The practical importance of these two advantages is dubious. Admittedly a 10-minute test is useful as a screen for grossly contaminated milk; but if the resazurin test is to be used as an index of keeping quality and the reduction of the dye observed to the pink stage, then there is practically no saving of time over the methylene blue test (Anderson and Wilson 1945). Watts and Stirling (1944), in a very careful investigation, found that the resazurin test, even when carried out on individual quarter samples, was of limited value for the routine diagnosis of mastitis, and practically valueless for the detection of milk from infected cows when mixed with normal milk; in fact, as much as 73 per cent. of the herd milk could be derived from cows suffering from mastitis without significantly altering the result of the resazurin test.

The disadvantages of the resazurin test are that the dye is not easy to standardize and is very sensitive to sunlight, that the colour change has to be followed by a comparator, and that the lilac and pink stages are not easily appreciated by persons whose vision is insensitive to red colours. In general terms it may be said that the resazurin test is more influenced by abnormal milk such as colostrum, late-lactation milk, milk from cows with mastitis, and by milk containing organisms with low reducing powers, but that the methylene blue test affords the better index of bacterial contamination of the milk.

(9) **The Laboratory Pasteurization Test.**—This consists in making a plate count

Soaps, the sodium and potassium salts of higher fatty acids, are mildly germicidal in themselves, but probably what disinfectant action they possess may be accounted for on the basis of mechanical removal of microorganisms by emulsification of the lipoidal secretions of the skin in which many bacteria become embedded. The surgical soaps, containing a disinfectant, are not as effective germicides as might be supposed, although somewhat more bactericidal than ordinary soaps.²¹ The slight bactericidal action of fatty acids is apparently attributable to the hydrogen ion. During recent years a group of substances similar to soaps, the sodium alkyl sulfates (such as Drene and others), have come into widespread use. These, like soaps, are anionic detergents. Some of these have been found to inhibit the growth of some bacteria in relatively high concentrations (0.1 per cent), but the activity is markedly selective, gram-positive bacteria being inhibited but gram-negative bacteria not affected.

Reduced surface tension in itself has little detrimental effect on bacteria, although it might be supposed that a germicidal substance which markedly reduced the surface tension of water would be more effective as a result of concentration at the bacterium-water interface. In the case of surface-active germicides it has been observed that wetting action and bactericidal proper-

ties are closely correlated. Whatever the mechanism, it has been found that wetting agents apparently increase the bactericidal action of undissociated phenols.²² In contrast with the soaps and alkyl sulfates, the salts of quaternary ammonium bases are cationic detergents. These have been of interest in recent years and appear promising as germicides, especially those having 12 to 16 carbon alkyl chains. Very many, perhaps a thousand, of these compounds have been synthesized and are marketed under various trade names such as Phemeral, Zephiran, Roccal and the like. These are definite mixtures of related compounds that differ in the number of carbon atoms in the alkyl chain. They are usually most effective on non-spore-forming gram-positive bacteria such as staphylococci and streptococci, and less so on gram-negative forms such as the enteric bacilli. The high degree of bactericidal activity which they show in the phenol coefficient type of test is, however, largely spurious.²³

Ethyl alcohol and ethyl ether, often used as skin disinfectants, are not good germicides. Their effectiveness probably lies in the solution of the lipoidal secretions of the skin and consequent mechanical removal of microorganisms. Absolute alcohol has little or no germicidal activity. The bactericidal activity of alcohol-water solutions increases with the addition of water but 50 per cent alcohol and less has little activity; 70 per cent is the concentration usually used for skin disinfection. Absolute propyl and isopropyl

title of "aggressin," did not long remain unchallenged. Wassermann and Citron (1907) contended that the aggressins were simply products of bacterial growth, or of bacterial autolysis, which could be prepared in the test-tube by suitable methods. Citron (1906) showed that the addition of bacterial extracts to living bacteria increased their virulence; that by the use of such extracts it was possible to immunize animals against experimental infection; and that the serum of such immunized animals conferred passive immunity on others. Bail and Weil (1906) maintained that the immunity produced by Citron with his bacterial extracts was far less effective than that produced by natural aggressins, and that it was different in kind; though it is not entirely clear on what differential criteria they relied in distinguishing anti-aggressin immunity from the varieties previously recognized.

Doerr (1906) criticized the aggressin theory on somewhat similar grounds, but emphasized particularly the fact that large doses of dead bacilli may cause death in experimental animals with the lesions described by Bail as characteristic of the aggressin effect. He also noted that when sub-lethal doses of killed cultures were added to sub-lethal doses of living bacteria the combined inoculum might cause a fatal infection of the aggressive-type. This additive effect did not appear to be in any way specific, but some killed cultures were more effective than others. For instance, dead typhoid or dysentery bacilli were more aggressive than dead staphylococci. In addition, Doerr demonstrated that aggressive exudates did, in fact, contain ordinary bacterial antigens, because a typhoid exudate gave well-marked precipitation with an ordinary antityphoid serum.

Sauerbeck (1907) also criticized Bail's hypothesis. He concluded, from the results of a large series of experiments, that aggressive exudates are not lacking in toxicity, since two or three times the amount that produces the characteristic aggressive effect will kill an animal within a few days in the absence of living bacteria; that the activity of a given aggressive exudate is in no way proportional to the virulence of the organism that produced it, but rather to its toxigenicity; that characteristic aggressive effects can be produced with toxic bacterial products that have been prepared in the test-tube; and that the aggressive action, whatever its cause, is entirely non-specific. His findings as regards the heat-lability of the aggressive bacterial products also differ from Bail's, since he states that they were not reduced in potency till they were heated at temperatures between 55° C. and 70° C.

Dudgeon's (1912) studies of the properties of exudates obtained from natural and experimental infections made it clear that one of the mechanisms in the total aggressin effect was a specific anti-opsonic action.

He obtained exudates from natural infections in man or from experimental infections in animals. The exudate, after the separation of as much material as possible by centrifugation, was mixed with an equal volume of normal serum, or of serum from an immunized man or animal. After 1 hour's incubation at 37° C. leucocytes and bacterial suspension were added to each mixture, the mixtures were re-incubated for 15 minutes and films were prepared from the contents, the degree of phagocytosis being determined in the usual way. In control tubes the exudate was replaced by saline. In each case the opsonic effect of the serum, and of the serum-exudate mixture, was determined against the bacterium causing the infection and against some related organism. The results shown in Table 73 illustrate an effect commonly observed. The exudate came from a subcutaneous staphylococcal abscess; the antiserum was from the infected patient; and the normal serum from an uninfected control. The sera and the serum-exudate mixtures were tested against the strain of staphylococcus grown from the abscess and against a strain of *Bact. coli*.

The exudate alone had a slight opsonic effect, but it specifically diminished the opsonic action of normal or of immune serum on *Staph. aureus*, leaving unaffected their opsonic action on *Bact. coli*. The substances responsible for this specific anti-opsonic effect were

Dyes

alcohols are likewise ineffective but show activity in aqueous solution, while absolute methyl alcohol is said to be bactericidal.

Dyes. The dyes are widely used in bacteriology both for staining purposes and as indicators. In addition, many of them show a marked bacteriostatic and bactericidal activity which is often specific in that it is manifested against one organism and not another. The incorporation of an appropriate dye in a medium will render it selective, i.e., it will favor the growth of some species of bacteria and inhibit that of others. In general, this specificity is correlated with the gram reaction, the gram-negative organisms are, for the most part, much less sensitive to dyes than are the gram-positive species. The activity of these compounds is affected by pH, the toxicity of the acid dyes increasing with acidity and that of the basic dyes increasing with alkalinity.

Many of the dyes such as the thiazins, oxazins and azo dyes are not particularly toxic for bacteria, dilutions of 1:1000 or less being required to inhibit growth. A number of the triphenyl methane dyes are, on the other hand, inhibitory in high dilutions. Malachite green, for example, inhibits the growth of *B. subtilis* in dilutions of 1:4,000,000 and staphylococci in 1:1,000,000, while higher concentrations, i.e., 1:30,000 to 1:40,000, are required to inhibit the colon and typhoid bacilli. Victoria green, a dichlor derivative of malachite green, is bacteriostatic to about the same degree. Brilliant green is active in even higher dilutions, inhibiting *B. subtilis* in a dilution of 1:15,000,000 and staphylococci in 1:4,000,000 and the typhoid and colon bacilli in 1:500,000.

The bacteriostatic properties of the triamino triphenyl methane dyes, the so-called rosanilins, are apparently associated with the substitution of alkyl groups in the amido side chains. Basic fuchsin, a mixture of the unsubstituted simple dyes rosanilin and pararosanilin, is relatively weakly bacteriostatic, dilutions of 1:500,000 being required to inhibit the growth of *B. subtilis*. Acid fuchsin, a mixture of various sulfonated derivatives of basic fuchsin, is likewise only weakly inhibitory and was formerly widely used in media as an acid indicator under the name of Andrade's indicator. On the other hand, methyl violet,²¹ a mixture of tetra-, penta- and hexamethyl pararosanilin, is markedly bacteriostatic and completely inhibits the growth of bacteria such as staphylococci, diphtheria bacilli and others in dilutions of 1:1,000,000 to 1:5,000,000. Approximately 150 times as much dye is necessary to suppress growth of the less sensitive gram-negative bacteria such as the colon and typhoid bacilli. There appears to be a correlation of bactericidal activity and basicity in the dyes as chemotherapeutic agents in recent years.²²

The acridine dyes, acriflavine and trypanflavine, have been of particular interest because of their therapeutic significance. The former is actively bacteriostatic in dilutions as high as 1:3,000,000 and the latter inhibitive to

²¹ Gentian violet is a more or less impure mixture of methyl violet and deinox. Crystal violet hexamethyl pararosanilin, is one of the constituents of methyl violet.

TABLE 194

Designation	General Conditions	Bacteriological Requirements	Remarks
Tuberculin tested	Must come from an Attested herd, or from a herd in which veterinary inspection and tuberculin tests are carried out as specified by the Minister of Agriculture and Fisheries.	Must not decolorize methylene blue in $4\frac{1}{2}$ hr. 1 May to 31 October, or in $5\frac{1}{2}$ hr. 1 Nov. to 30 April. ¹	(i) If bottled on farm, may be labelled Tuberculin Tested (Farm Bottled). (ii) If pasteurized, must not decolorize methylene blue in 30 min., ² or give a phosphatase reading of over 2.3 Lovibond units (iii) If sterilized, must pass the turbidity test.
Accredited	Must be derived from a single herd only. Herd must be subject to veterinary inspection and must not contain any animal known to react to tuberculin.	Same as for Tuberculin Tested milk. ¹	Designation valid only till 1 October 1954 when this grade was abolished.
Pasteurized	Milk must be kept at a temperature (i) of 145-150° F for at least 30 min., or (ii) of 161° F. for at least 15 sec., and be immediately cooled to 50° F. or below.	Must not decolorize methylene blue in 30 min., ² or give a phosphatase reading of over 2.3 Lovibond units.	Designation must be on cords must be preserved for at least a month. H.T.S.T. plant must be provided with an automatic flow-diversion valve. Sale of loose milk forbidden after 1 October 1954
Sterilized	Milk must be kept at a temperature of not less than 212° F for a time sufficient to ensure compliance with the turbidity test.	Must pass the turbidity test.	Sterilizing plant must be approved by the licensing authority, and must be provided with the specified thermometers and pressure gauges. Milk must be heated in bottles, and the bottles must be sealed afterwards with an air tight seal.

¹ If the sample is taken before the milk has been placed in bottles or other containers for delivery to the consumer (i.e. *producers' milk*), it must be transferred to the laboratory in an

milk, and a sample of as an evening milk be cooled to between before examination

The bottle or container for delivery to the consumer (i.e. *consumers' milk*) must be transferred to the laboratory in an insulated container. If it cannot be delivered to the laboratory within this time, it must be packed in ice. If the sample cannot be examined immediately it arrives at the laboratory, it must be cooled to between 32° and 40° F. and kept at this temperature for not more than 24 hours before examination. Any sample not reaching the laboratory on the day on which it is taken must be discarded unless it has been kept packed in ice since the previous day.

² The sample must be pac

staphylococci and similar organisms in 1:2,000,000 and to the relatively fragile gonococcus in dilutions of 1:10,000,000 to 1:50,000,000. The gonococcus is killed by exposure to the dye in dilutions of 1:80,000 to 1:400,000 within two or three minutes.

Gaseous Disinfectants. The use of bactericidal gases for the disinfection of rooms, dwellings and the like (fumigation or terminal disinfection) has declined markedly in recent years with no coincident increase in the prevalence of infectious disease. The commonly used gases, formaldehyde and sulfur dioxide (generated by burning flowers of sulfur), are probably not bactericidal as gases but in aqueous solution and are effective, therefore, only in the presence of adequate amounts of moisture (a relative humidity of 60 per cent or higher). Sulfur dioxide in aqueous solution (sulfurous acid) probably owes its germicidal qualities to its acidic nature. Formaldehyde, usually sold under the trade name of formalin (a 33-40 per cent solution of the gas in water), has greater penetrating power and is a more effective germicide than sulfur dioxide. Other gases such as hydrogen cyanide have little or no effect on bacteria. Although the value of terminal disinfection is open to serious question, that of disinfestation is well established and the gases, hydrocyanic acid in particular, are widely used for the destruction of rats aboard ship, etc.

Aerosols. The use of aerosols, bactericidal compounds finely dispersed in the air, for the destruction of air-borne pathogenic bacteria has been developed in recent years, especially by Robertson and his co-workers.²⁶ These investigators first used propylene glycol as a vehicle for bactericidal compounds but control experiments indicated that the glycol alone (volatilized by heat) was equally effective. Triethylene glycol is the glycol now most commonly used. The glycol is relatively non-toxic and the vapor may be breathed with impunity, but bactericidal concentrations of 50 per cent or higher are attained when droplets come in contact with suspended microorganisms. The rate of destruction of air-borne bacteria is in agreement with the assumption that the glycol molecules in the vapor state condense on the bacteria-containing droplets, and efficacy is associated with a low vapor pressure, high hygroscopicity and, of course, toxicity for the bacterial cell substance.²⁷ Other workers have used dispersed hypochlorite and ultraviolet irradiation to kill air-borne bacteria but these methods are not too promising. These results are of considerably more than ordinary significance in that they make possible the control of air-borne infection (p 231); the respiratory diseases have hitherto spread in the human population without hindrance.²⁸

The Specificity of Disinfectants. The marked specificity of the bacteriostatic and bactericidal activity of the dyes has been referred to above. The property of differential toxicity is not confined to these compounds alone, however, but is exhibited to some degree by many of the bactericidal chemicals. The hypochlorites, for example, while powerful germicides for most bacteria, have little effect on the tubercle bacillus. In general, the salts of the heavy metals are least specific in their action and dyes the most, with other

by Pasteurized milk, the milk had been filled into contaminated churns or bottles; in 1 the milk before pasteurization was heavily contaminated with *Staph. aureus* with the result that the milk after processing probably contained undestroyed staphylococcal enterotoxin; and in 1 outbreak caused by Pasteurized milk and

TABLE 195

RECORDED OUTBREAKS OF MILK-BORNE DISEASE IN GREAT BRITAIN IN 1938-52
(EXCLUDING TUBERCULOSIS, UNDULANT FEVER AND Q FEVER, AND OUTBREAKS
DUE TO MILK PRODUCTS SUCH AS ICE-CREAM, CHEESE, AND CREAM BUNS)

Disease	No of Outbreaks	No of Outbreaks in which Number of Persons affected is stated	No of Persons affected in these Outbreaks
Scarlet fever and septic sore throat	14	14	815
Diphtheria	6	6	37
Typhoid fever	8	8	57
Paratyphoid fever	13	13	309
Dysentery	21	20	2,630
Gastro-enteritis	48	44	3,109
Infectious hepatitis	2	2	153
Total	112	107	7,110

in the 2 outbreaks caused by Sterilized milk the milk was heavily contaminated with aerobic spore-bearing organisms which had apparently grown in the milk after processing

In the United States Armstrong and Parran (1927) recorded 612 milk-borne outbreaks occurring during the preceding 20 years, and Andrews and Fuchs (1918) recorded the figures for the 23 years 1923-45 (Table 196).

TABLE 196

OUTBREAKS OF MILK-BORNE DISEASE IN THE UNITED STATES OF AMERICA,
1923-45 (modified from Andrews and Fuchs 1918).

Disease	No of Outbreaks	No of Cases	No of Deaths
Scarlet fever and septic sore throat	202	19,190	182
Diphtheria	18	324	13
Typhoid fever	440	7,449	541
Paratyphoid fever	27	1,063	22
Dysentery	20	1,413	20
Gastro-enteritis	196	9,780	19
Miscellaneous	18	683	4
Total	921	39,902	801

This table again affords merely a conservative estimate of the frequency of milk-borne epidemics, and from previous experience there is reason to believe that many outbreaks are not recognized or are not recorded (Brooks 1933). It will be noted that the relative incidence of enteric fever is very much higher than in Great Britain.

Dolman (1941) in Canada collected records of 67 milk-borne outbreaks during

The Chemotherapeutic Drugs

compounds lying between these two extremes. Certain slow oxidizing agents such as potassium dichromate exert a selective bacteriostatic effect on gram-negative bacteria, and iodine is more efficacious against these microorganisms. Similarly, among the long chain aliphatic bases, the less strongly basic amines act on gram-positive bacteria for the most part, whereas the gram-negative organisms are more susceptible to the action of the stronger bases such as guanidines and quaternary amines.²⁹

Although it might be supposed that the specificity of disinfectants is an undesirable quality, it will be apparent on second thought that specific toxicity is often highly desirable. For example, a compound which is equally effective in the disinfection of both bacteria and tissue cells could not be used to advantage.

The Chemotherapeutic Drugs. The phenomenon of specificity also assumes great practical significance as the basis of chemotherapy of infectious disease. Ehrlich's discovery of salvarsan came as a result of a search for a "magic bullet"—a compound strongly germicidal for a given microorganism yet sufficiently non-toxic to the host that it could be injected into the tissues in effective concentrations. The discovery of chemical structures having these properties has been purely a matter of trial and error rather than rational theory, but once discovered, the active portion of the molecule may, of course, be modified to increase efficacy. decrease toxicity, etc. Successful chemotherapy has, in the past, been confined to certain spirochetoses and protozoan infections, the compounds showing activity including the arsenicals, compounds of antimony and of bismuth, certain dyes such as trypan red and the flavines, synthetic compounds such as atabrine and plasmochin, and certain naturally occurring substances such as quinine. Until relatively recently the bacterial diseases appeared to be, for all practical purposes, resistant to chemotherapy.

With the observation that the azo dye prontosil had marked chemotherapeutic activity in streptococcus infections, and the discovery of the active portion of the molecule, *p*-aminobenzene sulfonamide (sulfanilamide), a new series of compounds, known as sulfonamides, was found to be highly efficacious in the treatment of many bacterial infections. Many derivatives of *p*-aminobenzene sulfonamide have been prepared, radicals being attached to the nitrogen of the sulfonamide group, which show different solubilities, degrees of ionization, toxicity, rates of absorption and excretion, associated with differences in chemotherapeutic efficacy.³⁰

These compounds are bacteriostatic rather than bactericidal and appear to function *in vivo* by suppressing bacterial multiplication, the invading microorganisms being destroyed by the body defences, notably through phagocytosis by the cells of the macrophage system (p. 232). They do not affect the bacterial toxins to a significant degree.³¹

²⁹ Fuller, *Biochem. Jour.* 1942, 36 548.
³⁰ Cf. Bell and Robin, *Jour. Amer. Chem. Soc.*, 1942, 64 2905.

³¹ That is to say, there is apparently no clinically important effect, however, cf. Carpenter and Harbour, *Proc. Soc. Exp. Biol. Med.*, 1939, 41, 354, Hutter and Zahl, *Science*, 1942, 96 563.

country two methods are permitted. The Holder process consists in raising the milk to a temperature of 145–150° F., holding it at this temperature for 30 minutes, and immediately cooling it to 50° F. or below. If this process is carried out in properly designed plant free from mechanical defects (see Scott and Wright 1935, Dalrymple-Champneys 1935), and supervised by intelligent and conscientious operatives, it can be relied upon to destroy all pathogenic organisms in the milk. In the so-called High Temperature Short Time process the milk must be kept at a temperature of not less than 161° F. for at least 15 seconds and then cooled to 50° F. or below. (For description of planning and operation of pasteurizing plants see Report 1953.)

The adequacy of heat treatment may be controlled by the *phosphatase test* (Kay and Graham 1935, Kay, Aschaffenburg and Neave 1939, Memo. 1943, Report 1944), which depends on the fact that the enzyme phosphatase, which is normally present in milk, is destroyed by a temperature of 145° F. within 30 minutes or of 162° F. within 15 seconds. The test is carried out by incubating the milk in the presence of a buffered solution of disodium phenyl phosphate. The amount of phenol that is liberated is measured by adding Folin and Ciocalteu's reagent and estimating the depth of the resulting blue colour by a Lovibond tintometer or, more simply and approximately, by a Lovibond comparator. Raw milk gives figures of about 50 blue units, but in properly pasteurized milk the number of units is reduced to 2·3 or less. This is a most valuable test and can be used in practice to ensure that the processing of the milk is carried out satisfactorily. Phosphatase is slightly more resistant to heat than the tubercle bacillus, so that a negative phosphatase result is strong presumptive evidence in favour of the safety of the milk.

The objections that have been raised to pasteurization, though often made on apparently scientific grounds, are determined almost entirely by economic or political motives. The farmer, especially the producer-retailer, may not obtain such a high return for his milk if he has to pasteurize it himself or send it to a pasteurizing depot as if he sells it directly to the customer in its original raw and possibly dangerous state. Producer-retailers, moreover, are afraid that pasteurization will lead to their being gradually absorbed by the big milk combines, which can of course afford to pasteurize and bottle their milk under very much more favourable conditions than is possible for a small producer. Though appreciating the force of these motives, we must not allow the public health of the nation to be sacrificed to the financial interests of a small section of the community.

One of the chief objections that has been raised is that pasteurization lowers the nutritive value of the milk. The evidence for and against this contention has been reviewed by several workers (see Stirling and Blackwood 1933, Report 1934, 1936, 1937–39, Bendixen *et al.* 1937, Wilson 1942). The main effects of pasteurization by the Holder method at 145°–150° F. for half an hour followed by immediate cooling to 50° F. or below are as follows: (1) the cream line is reduced by about 10–30 per cent. (2) About 5 per cent. of the lactalbumin is coagulated. (3) There is a diminution of about 5 per cent. in the soluble calcium and phosphorus. (4) There is some destruction, amounting usually to about 10 per cent., and at the most to 25 per cent., of Vitamin B₁. (5) There is a variable diminution in the Vitamin C content, dependent on the degree of previous exposure of the milk to light, the presence of copper in the pasteurizing plant, and the amount of dissolved oxygen; at present, the average reduction is about 20 per cent. (6) Some of the iodine

stantially correct.³⁴ For example, the bacteriostatic action of a wide variety of derivatives of sulfanilamide is nullified by *p*-aminobenzoic acid and related compounds which will give it on hydrolysis. The relationship between the antagonist and drug is a quantitative one; the ratios usually reported vary from 1:1000 to 1:26,000 but are considerably nearer unity if the presence of antagonist in the test medium and the ionic concentration of the drug are taken into consideration.

It may be noted that, as a corollary, specimens of blood, urine or other body fluids taken from an individual undergoing sulfonamide therapy may contain sufficient amounts of the drug to inhibit bacterial growth when they are cultured. The inhibiting effect may be avoided by including *p*-aminobenzoic acid in the culture medium; a concentration of 5 mg. per 100 ml. is adequate.

With generalization of the idea of competitive inhibition of essential metabolic reactions, antagonisms to other bacterial vitamins may be predicted and tested. This has been done, especially by McIlwain. It has been found that the modification to produce an analogue may vary and may include the replacement of a carboxyl group with a sulfonic acid or sulfonamide radical, or by a ketone, by the substitution of one atom for another in the ring system of aromatic metabolites, the replacement of alkyl side chains of ring systems with halogens, etc. For example, sulfonic acid and sulfonamide analogues of nicotinic acid and pantothenic acid have been prepared by substitution of $-\text{SO}_3\text{H}$ or $-\text{SO}_2\text{NH}_2$ for a carbonyl group and have been found to be specifically antagonistic and inhibitory. Similar results have been obtained with pyriethamine, the pyridine analogue of thiamine. The reverse kind of experiment has been carried out also. Iodinin, the di-N-oxide of a dihydroxy-phenazine, is a pigment produced by *Chromobacterium iodinum* which inhibits the growth of certain bacteria. The inhibitory effect can be nullified by certain anthraquinones and naphthaquinones, from which it may be inferred that quinones play some part in bacterial metabolism, possibly in the transport of hydrogen. As yet none of the analogues tested have had practical chemotherapeutic activity though some effect may be observed; large doses of thiopanic acid (pantyltaurine, an analogue of pantothenic acid) protects rats against lethal doses of hemolytic streptococci.

It may be noted in passing that the generalization of this theory seems to remain valid when carried over to higher organisms. Thus, symptoms of vitamin deficiency may be produced in experimental animals by feeding an analogue of the vitamin, e.g., pyriethamine, glucoascorbic acid, iso-riboflavin and the phenazine analogue of riboflavin, β -acetyl pyridine (an analogue of nicotinic acid).

The mechanism of competitive inhibition is in most cases more complex than here indicated. It is frequently assumed that analogues compete with metabolites acting as coenzymes, but in general the evidence indicates that the competition occurs when the metabolite acts as a substrate rather than a coenzyme. As a substrate, the metabolite is synthesized into a more complex molecule which functions as a coenzyme, or it may be degraded prior to synthesis. Thus, *p*-aminobenzoic acid is a part of folic acid and competition

³⁴ See the reviews by Wooley: *Advances in Enzymology*, 1946, 6:129, *Physiol. Rev.*, 1947, 27:308; Hotchkiss: *Ann. Rev. Microbiol.*, 1948, 2:183

The cleanliness of churns and bottles can be assessed by means of a plate count carried out on suitable rinsings. The method of examining bottles is described in full by Hobbs and Wilson (1913) in their report on the comparative efficacy of different methods of washing and sterilizing bottles. Briefly it consists in taking 6 or 12 representative bottles, adding to each 20 or 30 ml. of $\frac{1}{4}$ strength Ringer's solution according to the size of the bottle, rolling the bottle to ensure that the whole of the internal surface is thoroughly wetted, allowing the bottle to stand for 15-30 minutes, again rolling it, and then preparing duplicate plates each with 5 ml. of the rinsings. The plates are prepared with Yeastrel milk agar (Memo 1937), and are incubated one at 22° C. and the other at 37° C. for 3 days, after which the colonies are counted. The following standards are generally accepted in this country:

Less than 600 colonies per bottle	.	.	.	Satisfactory
600 to 2000	"	"	"	Fairly satisfactory
Over 2000	"	"	"	Unsatisfactory

The examination of churn rinsings is carried out in an essentially similar way.

The Mechanism of Antibacterial Action

apparently occurs in the synthesis of the vitamin. Similarly, pyriothiamine does not compete with thiamine pyrophosphate when the latter functions as co-carboxylase, but rather competition appears to occur in the synthesis of the coenzyme from thiamine. It was early assumed that, if a compound is required by certain bacteria, it is an essential metabolite for other bacteria also which do not show the requirement because they are able to synthesize it, it would appear to follow that a drug could compete with a vitamin either preformed or after synthesis by the microorganism. It is not quite so simple as this, however, for it has been found that bacteria which do not require thiamine, for example, are able to split pyriothiamine into pyrimidine and pyridine in the same way that thiamine is split into pyrimidine and thiazole components, and that organisms which cannot synthesize thiamine also lack the ability to split pyriothiamine and are susceptible to its inhibitory activity. Such somewhat indirect relationships to the better known metabolic reactions of bacteria probably account, to some extent at least, for evidence which appears to be inconsistent with a hypothesis of direct competitive inhibition.

The Effects of Antibacterial Compounds The ways in which antibacterial substances affect the cell so as to produce either irreversible changes in the cell organization resulting in death, or an inhibition of processes essential to reproduction, vary. Available evidence indicates, as might be expected, that a variety of effects may be produced by oxidizing agents, a saturation of thiol groups of protein by, for example, the substitution of halogens such as iodine in the ring structures of aromatic amino acids, obviously alters the organization of the cell on a macromolecular level to such an extent that normal metabolism cannot continue. Bactericidal substances of the phenol group apparently act in this way in that phenol is surface-active and by orientation of the hydroxy groups reacts with free amino groups of the cell proteins.²¹ Even those substances which appear to be general protoplasmic poisons, however, may show some specificity of action, there is evidence that chlorine, for example, first affects a triosephosphate dehydrogenase system.²²

Or the effect may be somewhat more localized as in the case of the basic dyes which react with nucleotides, it is not unreasonable to suppose that flavine, is antagonized by nucleotides, it is not unreasonable to suppose that the hereditary mechanisms of the bacterial cell are made up of nucleoprotein and their inactivation by nucleotides, it is not unreasonable to suppose that inhibits proliferative processes. Similarly, the surface-active detergents are antagonized by lipids, e.g., the anionic detergents by cephalin, and there is some reason to believe that they alter the permeability of the cell wall to such an extent that the cell dies.

Interference, by competitive inhibition or otherwise, with specific metabolic reactions is, perhaps, more obvious when these are essential to the metabolism of the cell. Such metabolic reactions may be the energy yielding oxidations of the respiratory process and, as indicated elsewhere, the bactericidal efficacy of many compounds may be estimated as accurately by inhibition of oxygen

²¹ See Fox and Lodge *Trans. Faraday Soc.*, 1945, 41:359.

²² Green and Stumpf *Jour. Amer. Water Works Assn.*, 1946, 38:1301.

uptake in respirometers as by methods using death as an end point. Many of the important antibacterial substances, however, do not appreciably affect the respiratory mechanisms and there is reason to believe, in some cases at least, that they interfere with synthetic mechanisms; for example, there is some evidence that the sulfonamides interfere with synthesis. Other compounds, such as azide and dinitrophenol, actually increase oxygen uptake, in the presence of carbohydrate substrates, but the increased oxidation is due to a prevention of assimilation of carbon by the cell. It will be clear that, while information as to the precise point of attack of antibacterial substances on cell metabolism is far from complete, a variety of mechanisms is not only possible but operative.

Potentiating and Interference Effects. As yet unexplained are the results of mixing antibacterial substances. In some cases, of course, the antibacterial activity of two substances is simply additive. In others, however, the effect is potentiating in that the activity of the combined substances is greater than a purely additive activity, and the activity of some compounds may be enhanced by mixture with inactive ones. Such potentiating effects are observed in the combination of penicillin (p. 131) with gramicidin (p. 128) or sulfonamides, or in the combination of sulfonamides with azochloramide. The activity of sulfonamides may be enhanced by mixture with inactive substances such as carbamates, urea, asparagin, and the like. In still other instances, notably the incorporation of bactericidal substances with soaps, the combined effect is less than an additive one.

Factors Influencing Disinfection. The process of disinfection or bacterial death is often, in part at least, a chemical reaction and is, therefore, subject to a variety of influences which affect the velocity of such reactions. The most important of these influences is the concentration of the reacting substances, *i.e.*, the concentration of disinfectant and the numbers of bacteria present. The effective concentration of disinfectant is, in turn, dependent upon two other factors, first, the presence of moisture, which makes possible coagulation by heat, and ionization of the bactericidal salts, and acts as a solvent and suspending medium in which there may be intimate contact between the disinfectant and the microorganism; and, second, the presence of extraneous organic matter. Many chemical disinfectants act through a combination with the protein of the cell and, if extraneous organic matter is present, will, of course, react with this inert material, thereby reducing the effective concentration. Disinfectants vary widely in the degree to which their bactericidal properties are affected by organic matter. The salts of the heavy metals are rapidly precipitated by organic material, while compounds such as phenol and the cresols are only slightly affected. The rate of destruction by heat is also affected by the presence of organic matter—organisms embedded in a mass of fecal material, for example, are protected from heat for a short time. The process of disinfection by germicides or by heat is influenced by temperature, the velocity of the reaction increasing with rise in temperature. The pH likewise influences the rate of bacterial destruction not only by heat but by many chemical compounds, the velocity, in general, being least at neutrality and increasing with increase in acidity or alkalinity. A number of other factors such as the presence of salts, etc., affect the rate of disinfection but generally not sufficiently to be of practical importance.

The Dynamics of Disinfection

From the practical point of view, the time of exposure of bacteria to a given disinfectant is of considerable significance and, of course, bears an inverse relation to the rapidity of killing. The time allowed for the destruction of bacteria is determined not only by the factors discussed above but also by the kind of bacteria that are to be killed. In certain cases the specificity of a disinfectant may be so marked that it must be taken into consideration. For example, the relative toxicity of hypochlorite for the tubercle bacillus referred to above precludes its use in the disinfection of tuberculous sputum. Bacterial spores are much more resistant to heat and chemical disinfectants than are the vegetative cells, and considerably more time must be allowed for their destruction. The vegetative cells of some bacteria may be somewhat more resistant than those of others, but, for the most part, such differences are too small to be of practical significance.

The Dynamics of Disinfection. Quantitative studies on the rate at which bacteria are killed by lethal agents have indicated that in many instances the organisms die at a logarithmic rate, i. e., if the logarithms of the numbers of viable organisms are plotted against time, the points tend to fall on a straight line. This phenomenon has been observed in the death of both spores and vegetative cells under the influence of chemical disinfectants or moist heat and also occurs in the death of bacteria in old cultures. The velocity of the reaction, the slope of such a line, depends upon the concentration and kind of disinfectant, the nature of the organisms—whether spores or vegetative cells—and other factors which influence the process of disinfection. This logarithmic rate likewise describes the course of a monomolecular reaction, and this fact has led some to conclude that bacterial death is a monomolecular chemical reaction. Although the killing of bacteria by some disinfectants is undoubtedly

a chemical process, as for example the precipitation of constituent protein as proteinates of heavy metals, the evidence does not justify the conclusion that the reaction is monomolecular. The fallacy is the old one of confusion of correlation and causality under the slightly different guise of description and mechanism. Experimental evidence has indicated that while such semilogarithmic plots may often be fitted with a straight line, others are best fitted by sigmoid curves, the death rate being more rapid in the beginning in some cases and more rapid at the end in others or even highly irregular. Some workers³⁷ have concluded that one of the more important determining factors is a graded biological resistance of the cells in the bacterial population, an explanation that is supported by general biological considerations. Undoubtedly the phenomenon of bacterial death is a complex of interrelated factors whose admixture with the mechanics of the mass law results in the parameters determined by mathematical means. Of practical importance, however, is the fact that in disinfection by chemicals and by heat there is a minority of cells, possibly more resistant, that survive long after the majority have perished and that must be destroyed in order to obtain complete sterilization.

The Standardization of Disinfectants. The relative bactericidal efficiency of the chemical disinfectants is a point of considerable practical importance. The value of a quantitative method for the determination of the killing power of germicides was recognized early in the development of bacteriology, and experimental investigation led to the establishing of a standardized technique which made possible the determination of the bactericidal power of a given chemical compound relative to that of phenol. The numerical value so determined is termed the *phenol coefficient* and is presumed to indicate whether, and to approximately what extent, the unknown is a better or poorer germicide than phenol. Later methods of standardization have grown out of this procedure. The phenol coefficient of a disinfectant used against the typhoid bacillus is calculated as follows:

Divide the greatest dilution of the disinfectant capable of killing *S. typhi* in ten minutes but not in five minutes by the phenol dilution which so kills this, and divide these figures one into another. In order not to convey a false idea of the accuracy of the method the coefficient is calculated to the nearest 0.1 point if under 1, to the nearest 0.2 point if between 1 and 5, to the nearest 0.5 point if between 5 and 10, and to the nearest 1.0 point if between 10 and 20.

For example, if a 1:90 dilution of phenol kills in 10 minutes but not in 5, and a 1:100 dilution does not kill in 10 minutes, the former is taken as the end point; and if a 1:350 dilution of the unknown disinfectant kills in 10 minutes but not in 5, while 10 minutes' point is the 1:350 dilution. The phenol 3.89 or 3.9, and the unknown has, by The conditions regarded as standardized, have been defined by the Food and

Drug Administration.³⁸

The effect of extraneous organic matter on the bactericidal power of a disinfectant is commonly taken into consideration by carrying out the test with and without added organic matter. Three per cent of dried fecal matter or dried yeast may be added to the bacterial suspension or the organisms may be

suspended in 50 per cent serum. It is important to recognize that bacteria differ considerably in their resistance to phenol, staphylococci, for example, being much more resistant than the typhoid bacillus, so that in strict accuracy it is necessary to specify "typhoid phenol coefficient," "pneumococcus phenol coefficient," etc.

It is open to question as to whether compounds whose structure and chemical and germicidal activity differ greatly from that of phenol may legitimately be compared with this standard disinfectant. In recent years some workers have departed from the standard procedures, altering them to suit individual requirements. The phenol coefficient of an alcoholic solution of a compound insoluble in water obviously has little value, as has that determined on an acid or alkaline solution of a compound only slightly soluble at neutrality.³⁹ The simple statement that a given germicide has such and such a phenol coefficient has, then, little meaning.

Even assuming, however, that the standard phenol coefficient procedure be rigidly adhered to, the test itself is open to serious criticism. The end point to be determined is, clearly, sterility—all the test organisms must be destroyed. The quantitative studies discussed above have shown that although destruction may proceed at a regular and rapid rate for a time, the asymptotic tendency of the survival curve indicates that sterility or complete destruction is not a desirable end point in that it is one that is difficult to determine with a reasonable degree of accuracy. The practical consequences of the use of this end point appear in the form of aberrant results when the time variable is altered. If the end point be taken as sterility in two and one-half minutes as in the original Rideal-Walker method, the phenol coefficient of HgCl_2 is somewhat more than 2, but if the time taken is thirty minutes as in the Chick-Martin modification, HgCl_2 has a phenol coefficient of 550.⁴⁰

Furthermore, the phenol coefficient test does not take into consideration the temperature coefficient of the disinfectant under examination, which differs with the test organism,⁴¹ nor does it measure the effects of changes in concentration. A rise in temperature increases the activity of phenol and similar compounds much more than that of the salts of heavy metals; doubling the concentration of phenol increases its bactericidal activity approximately 64 times, while a similar increase in the concentration of HgCl_2 only roughly doubles its activity.

It is generally agreed that the rate of killing, *i.e.*, the reaction velocity constant, is a much more accurate measure than any value whose derivation depends upon a sterility end point. The relation between concentration of disinfectant and time required for killing is an exponential one and the reaction velocity constant, k , is given by the expression:

$$k = C^n t$$

when C is the concentration, n a constant characteristic for each disinfectant, and t is time. The temperature coefficient may, of course, be determined ex-

The Standardization of Disinfectants

perimentally for each disinfectant. It will be clear that this kind of characterization of the bactericidal activity of a given compound is much more informative than the usual type of phenol coefficient, no matter how precisely the conditions of the test are defined. It is not, however, generally used for routine work.⁴²

The practical value of a disinfectant is not always indicated by tests made under the controlled conditions of the laboratory. Hydrogen peroxide, for example, may give a quite respectable phenol coefficient but, when applied to an abrasion, is so rapidly decomposed under the influence of tissue catalase that its germicidal powers are almost immediately exhausted.

On the other hand, a given disinfectant may be so highly toxic for tissue cells that it has no practical value. Salle and his associates⁴³ have proposed a "toxicity index" which takes into consideration not only the germicidal activity of a compound but its toxicity for tissue as well. For example, Witlin⁴⁴ determined the concentration of bactericidal substances lethal for the chick embryo and calculated a toxicity index by using the concentration of the bactericide in grams per milliliter killing the test organism, *Staphylococcus aureus*, in ten minutes but not in five as the numerator, and the chick embryo MLD in grams for the denominator. Representative values were: phenol (1.20)—1.18, $HgCl_2$ (1.1000)—0.62, tincture of iodine—0.044, sodium hypochlorite—1.39, mercurchrome (1.50)—13.3, and values ranging as high as 9.1 for various organic mercurials. Spaulding and Bondi⁴⁵ have developed an infection-prevention toxicity test in which the tip of a mouse tail is contaminated with bacteria, the tail dipped into the solution of disinfectant, and then the tip is removed and placed in the peritoneal cavity. The highest dilution of the disinfectant protecting 50 per cent of the mice is taken as the numerator, and the greatest concentration allowing survival (from poisoning) of the test animal is taken as the denominator, to give a ratio or infection prevention-toxicity index. Such toxicity indices are of considerable practical importance in the case of skin disinfectants. There is as yet no standard method for their testing.⁴⁶

The whole question of the evaluation of disinfectants is beset with many difficulties, both theoretical and practical, and to date remains an open one to which no entirely satisfactory answer has been supplied.

⁴² For applications of this approach see, for example, Witell Jour Hyg. 1942, 42 124 339, Irwin *ibid.*, 1942, 42 328, it has also been studied extensively by Jordan and Jacobs Jour Hyg. 1944, 43 275, 363, *ibid.*, 1945, 44 210, Ann. Appl. Biol. 1945, 32 221. Jour Hyg. 1946, 44 243, 249, 421

Further light has been thrown on the probable nature of the anti-opsonic substances in aggressive exudates during the prolonged and detailed study of the factors involved in antipneumococcal immunity.

Rosenow (1907) described extracts and autolysates of virulent pneumococci which inhibited the phagocytosis of relatively avirulent pneumococci; he suggested the name *virulins* for the active substances concerned.

Cole (1917) observed that empyema fluids from pneumococcal infections contained soluble substances which specifically neutralized the protective antibodies in an antipneumococcal serum, and that similar substances might be present in the blood of rabbits suffering from experimental pneumococcal infection. He showed that, when an antipneumococcal serum was injected intravenously into a rabbit previously infected with the same type of pneumococcus, the protective antibodies disappeared very rapidly from the blood, and that a similar phenomenon could be demonstrated in patients severely ill with lobar pneumonia.

More recent studies on the antigenic components of bacterial cells (Chapter 8), and the demonstration that sensitization to the phagocytic action of polymorphonuclear cells and macrophages depends upon the union of antibody with an antigenic component situated at the surface of the bacterial cell, suggest that the substances responsible for the specific anti-opsonic effects of aggressive exudates are dissolved bacterial antigens. Landsteiner's demonstration of the inhibition of antigen-antibody reactions by simple haptens (see p 297), and the *in vitro* reactions of specific bacterial polysaccharides that fail to stimulate antibody production *in vivo*, indicate that bacterial haptens, as well as complete antigens, may be expected to exert this anti-opsonic effect.

There is good evidence that this is actually the case. Sia (1926) has studied the action of the type-specific polysaccharides of Type II and Type III pneumococci on the growth of these organisms in serum-leucocyte mixtures from the rabbit and from the cat. The pneumococci were of relatively low virulence and developed very poorly in both the serum-leucocyte mixtures employed. The addition of minute amounts of Type II polysaccharide greatly increased the growth of Type II pneumococci, but had little effect on the growth of the Type III organisms. The addition of minute amounts of Type III polysaccharide greatly increased the growth of Type III pneumococci, but not of Type II.

Felton and Bailey (1926) also demonstrated the aggressive action of Type II polysaccharide, by injecting it into mice, together with relatively avirulent pneumococci of the same type, and inducing a fatal infection. Type I polysaccharide had analogous effects (Ward 1930), and the anti-bactericidal effect proved to be due to the specific inhibition of phagocytosis (Ward and Enders 1933). The anti-phagocytic action of the Type I polysaccharide as prepared in the laboratory was not so pronounced as that of Type II and Type III polysaccharides. Nor was it as pronounced as that of extracts of pneumonic lungs infected with Type I pneumococcus (Ward 1932). The discrepancy was later resolved by the discovery that the polysaccharide preparations, unlike native polysaccharide, were not acetylated (see Chapter 8). Acetyl polysaccharide proved to be fully anti-opsonic (Enders and Wu 1934). The aggressive effect of the pneumococcal polysaccharide in human infections is suggested by the work of Cole (1917) and Park and Cooper (1928), who record that a fatal outcome in cases of lobar pneumonia in man is frequently associated with the presence in the blood of specific soluble antigen in amounts greater than can be neutralized by the antibodies that the patient has produced.

Downie (1937) observed an aggressin-like effect of Type I pneumococcal polysaccharide. Mice immunized with a single dose of polysaccharide were resistant to a given dose of Type I pneumococci. When this dose was injected together with 0.05 mgm. of the same polysaccharide, the immunity was in most cases abolished. Nye and Harris

BACTERIAL HEREDITY AND VARIATION

Before the development of methods of isolating bacteria in pure culture many observers regarded these organisms as members of a markedly homogeneous group, possibly of but a single species, which showed a high degree of morphological variation. The interconversion of coccus, bacillary and spiral forms was considered to be of common occurrence and, in consequence, the observed morphological differences among the bacteria were held to be of no significance. This doctrine, designated as *pleomorphism*, reached its height in 1877 with Nageli, who postulated but a single species to which all bacteria belonged. It should be noted that the term *pleomorphism* included not only morphological variation but equally facile alterations in virulence; the innocuous hay bacillus (*Bacillus subtilis*), for example, presumably could change suddenly into the highly virulent anthrax bacillus.

The development of pure culture techniques by Koch and others swung the pendulum to the other extreme, and the doctrine of *monomorphism* became predominant. It was held by Koch and other extremists, whose camp the great majority of bacteriologists soon joined, that a given bacterial species existed in one and only one form, and that aberrant forms were either evidence of contamination of the pure culture or were the so-called involution or degenerative forms which were dead or dying and therefore had no significance. This *monomorphism* was confined largely to bacterial form and, although abrupt changes such as the conversion of the hay bacillus to the anthrax bacillus were denied, alteration in the virulence of pathogenic bacteria was not regarded as inconsistent with an absolute constancy of form.

Despite the currency of this extreme *monomorphism*, evidence began to accumulate which indicated that, though most bacteria showed a remarkable constancy of form, morphological and physiological variation of these organisms is not uncommon. The last thirty or forty years have seen the development of an extensive literature on this subject. Much of the evidence which has accumulated is of just sufficiently inconclusive character that widely different interpretations may be made. Contemporary workers fall into two groups in this respect—the conservatives, a group which includes the majority of workers, who still adhere to the doctrines of Koch and his school in a modified form and who accept the well established variations as observed facts whose full significance is as yet not apparent, and the radicals, who profess to see evidences of complex life cycles, conjugation, sexual reproduction and kindred phenomena in the reported observations. It is not improbable that a sound interpretation lies somewhere between these views.

Bacterial Heredity and Variation

The biological significance of observed variations and their relation to similar phenomena occurring in the higher forms of life are difficult to assess. The difficulties stem in part from a strong tendency to regard bacteria as somehow "different" from other living organisms. This inherently sterile concept has arisen partly because of the apparent absence of a morphologically discrete nucleus in the bacterial cell, partly because the characteristics of bacteria which vary are generally not directly comparable to the genetically determined characters which are studied in the higher organisms, and partly because the bacteria are subject to the influence of unique environmental factors.

While it seems not unlikely that the chromatinic bodies described by Robinow (p. 51) represent an organized nucleus in the bacterial cell, there is as yet no indication of an intranuclear differentiation into structures analogous to chromosomes. Present evidence suggests that nuclear division, if the division of chromatinic bodies may be so regarded, is not as complex, at least morphologically, as the process of mitosis. While there is evidence, as will appear, of a spatial orientation of hereditary determinants, no corresponding morphology is as yet apparent, and the cytological techniques so essential to the understanding of the genetics of higher organisms have not been applicable to the bacteria.

The differential characters which serve to distinguish bacteria from one another are, in general, of a greater degree of fineness than those which the biologist is accustomed to use. The bacteriologist is concerned with characters not so gross as the red and white eyes of *Drosophila* but which might be considered analogous to the individual enzyme systems operative in the formation of red and white eyes. When such characters have no counterpart among those known to be of fundamental significance to the higher organism, and most if not all of them as yet have not, it is extremely difficult to judge whether they are of deep-seated importance to the cell or whether they are biologically trivial. Loss of virulence by a pathogenic organism, while of great practical importance to its prospective host, may be of only minor significance to the bacterium. Analogies are, then, difficult to draw and are always of doubtful validity.

Not only are the environmental factors which affect the bacterial cell to some degree peculiar to unicellular organisms of minute dimensions, but the essential obscurity of the bacterial environment is, to no small degree, a consequence of the limits of human imagination. Some aspects of this bacterial environment are known. For example, the tremendously exaggerated effect of surface tension on objects as small as bacteria must profoundly influence the bacterial form. The continuous molecular bombardment to which these organisms are subject and to which, because of their small size, they respond with the dancing motion of brownian movement, may be a factor which influences their structure and rigidity of form. The predominance of interfacial phenomena in the bacterial world of near-molecular dimensions undoubtedly contributes to its general character. There is evidence, for example, that hydrogen ion activity and reducing intensities may be quite different at interfaces from what the observer of gross phenomena assumes them to be. The environment to which these and undoubtedly other phenomena

character is, clearly, an abstract one, and the interpretation of morphological or physiological changes taking place under such circumstances is, to say the least, difficult.

From these considerations it is easy to understand how bacteria can come to be regarded as "different" without real justification for such a belief. It cannot, then, be emphasized too strongly that, so far as is known, bacteria do not differ in any essential way from other living cells and any interpretation of variation or other phenomena must rest on a sound biological foundation.

Before discussing the kinds of bacterial variation which are observed, two concepts fundamental to the general problem must be considered. One of the most important of these is that of the "normal" morphological or physiological state of a bacterium. The anthropocentric tendencies of the human mind

Fig. 24. The morphology of *Rhizobium*. Left, a smear from a pure culture on laboratory media; note the regularity of the "normal" bacillary morphology. Right, smear from a clover root nodule showing swollen, branched and coccoid forms, the so called bacteroides Fuchs, $\times 1050$.

stimulate the belief that the normal form and functions of a bacterium are those which are manifest in culture on the ordinary laboratory media. Certain evidence suggests, however, that the term normal is but a relative one. The symbiotic nitrogen-fixing organisms show a relatively constant "normal" morphology on the usual laboratory media, but in the root nodule they are found in a variety of bizarre forms designated as bacteroides (Fig. 24). Which, then, may be considered to be the "normal" form, that observed in the laboratory or that shown by the organisms in what might be regarded as their natural habitat? The physiological differences between bacteria in pure culture and those in the mixed cultures occurring in nature have been discussed in Chapter 4. Clearly, then, the term normal, although an extremely useful one, cannot be taken to have real meaning.

The second concept is that of bacteria in terms of populations. The existence of bacteria as population groups composed of enormous numbers of individuals and a rapid rate of cell division results in a compression in both time and space of biological processes. The resulting exaggeration of variabil-

Bacterial Dissociation

ity of the bacteria as compared to that of other living organisms, coupled with the selective effect of population pressure as numbers approach a limiting density, undoubtedly contributes in very large part to the apparent flexibility in the response of bacteria to environmental conditions. The importance of the population aspect of bacteria has only recently become more generally recognized,¹ though inter- and intraspecies relationships at the population level of other organisms constitute a large part of ecology.

Here bacterial variation will be considered under two general heads, the kinds of variation observed, and the mechanisms operative in such variation.

OBSERVED VARIATIONS OF BACTERIA

Bacteria have been found to vary, sometimes widely, in all the characteristics made use of in their differentiation and identification. These include morphology, both macroscopic and microscopic, physiological properties, including ability to produce disease; and immunological character. Changes may appear suddenly, i.e., in a single subculture, or they may become apparent only gradually as in aged cultures or over many transplants or animal passages and some hundreds of generations. The rapidity of appearance, however, cannot be taken to have fundamental significance and, in fact, in many instances is subject to experimental manipulation. Variants may appear apparently spontaneously, or may be seemingly induced by making the culture medium mildly and specifically toxic, as by the inclusion of lithium chloride, antiserum, antibacterial substances and the like, or by making it selective so that the expected variant is given enhanced survival value as, for example, by including a sugar in the medium in attempts to isolate fermenting variants of a non-fermenting parent strain. The relative importance of the characters subject to variation is by no means clear, and some may be biologically trivial while others are a reflection of deep-seated changes within the cell. It may be emphasized that relative biological importance is not necessarily related to practical importance.

MORPHOLOGICAL VARIATION

Variation in the morphology of bacteria may be considered under two general heads, colonial morphology or that of masses of cells, and the morphology of individual bacterial cells.

Bacterial Dissociation. A remarkable type of bacterial variation, whose most obvious outward manifestations is a change in the type of colony formed on semi-solid media, was observed by Baerthlein in Germany (1918). Adwight in England (1921) and de Kruif in the United States (1921). The phenomenon was termed by de Kruif bacterial or microbial dissociation, a term which has, in spite of certain undesirable features, been generally adopted. The ordinary laboratory culture, particularly old broth cultures, when plated out on an agar medium develops into two kinds of colonies; one, smooth (S), round, convex and shining; the other, rough (R), irregular, flattened and wrinkled. In addition to these obviously different extreme colony types (Fig. 25), all degrees of intermediate (SR and RS) types may usually be found. The transformation of the S form, usually regarded as the

cultures by Braun.² Similarly, the inclusion of antiserum to one dissociative form markedly favors the development of the heterologous form.

The G Colony. Another type of colony, the so-called G type, although apparently seen by earlier observers in 1910 and 1911, was brought to general notice by Hadley and his co-workers. These colonies are very small, 0.05 mm. or less in diameter, and appear to be made up of small cells of diverse morphology. They may be regarded as variants with an inherently lowered metabolic rate which perhaps permits survival under unfavorable conditions.³

L Variation. Perhaps related to G colonial variation is the so-called L variation. The normal mode of reproduction of the pleuropneumonia-like organisms and the non-sporulating obligate anaerobic bacteroides includes the formation of greatly swollen cells or large spherical bodies from which bacilli or granular forms are liberated (pp. 540 and 548). The latter give rise to very minute colonies similar to the G colony. This phenomenon has also been reported as occurring in other bacteria such as *Proteus*, but with somewhat less convincing evidence.

Variation in Cell Structures. As indicated above, colonial morphology is in part a function of the morphology of the individual cells making up the colony, and one of the most important factors in the differential morphology of the S and R variants is the occurrence of hydrophilic polysaccharide on the surface of the cell. As pointed out elsewhere (p. 42), this frequently takes the form of a layer or morphologically demonstrable capsule on the outer surface of the cell.

Capsules. Capsule formation or, from the physiological point of view, the synthesis of capsular substance usually of polysaccharide but sometimes of polypeptide nature, is very common among the bacteria, but a morphologically demonstrable capsule is not always apparent. Capsule formation is dependent in large part on the environment, and the most favorable medium in the case of pathogenic bacteria in which capsule formation is associated with virulence is the body of the susceptible animal. The anthrax bacillus forms a heavy capsule in the infected animal, but there is little or no evidence of a capsule when the bacilli are cultivated on laboratory media. The pneumococcus, likewise heavily encapsulated in the infected animal, also forms a capsule in artificial media, but the capsule is best developed when the medium is enriched with blood or serum and carbohydrate. Among the pathogenic forms, capsule formation tends to diminish with continued cultivation on artificial media, probably because these furnish a somewhat less than optimal environment, and is restored by animal passage of the bacteria.

The heavily encapsulated saprophytic bacteria, such as the dextran- and levulan-forming cocci of the genus *Leuconostoc*, show no tendency to loss of capsule formation in culture provided that carbohydrate is supplied, and it seems probable that the artificial medium is more nearly optimal than it is in the case of the more fastidious pathogenic bacteria. In general, then, capsule formation is determined in large part by the environment, may be a quantitative matter and is reversible.

Capsule formation may be specifically inhibited, however, the most effective

Involution Forms

tive means being the inclusion of antiserum to the capsular material in the culture medium. The loss of capsule formation under such circumstances, or when it is relatively complete by thorough prolonged culture on artificial media, results in the S-R dissociation, and the lack of a capsule is characteristic of the rough variant. As indicated above, this loss is also reversible, though frequently only with considerable difficulty. Whether it is to be regarded as basically different from a gradual diminution in the amounts of capsular substance synthesized through continued cultivation in a less than optimal environment is not clear. The relatively rapid appearance of non-encapsulated variants may be a consequence of the highly selective effect of antiserum rather than indicative of a mutation-like change.

Flagella. The occurrence of flagella on motile bacteria is also subject to variation. There appears to be little or no variation with respect to numbers or position of flagella, but their presence or absence is variable. Non-motile variants of motile bacteria are occasionally, though not commonly, observed, and these appear to be stable forms with little tendency to reversion to the motile form. In the case of very actively motile bacteria such as *Proteus*, colonial morphology is affected by motility in that the motile bacteria "swarm" and the growth spreads in a thin film over the surface of an agar medium, while the non-motile variants form discrete colonies.

The formation of flagella is subject to environmental influence also. Actively motile species kept in stock culture on laboratory media tend to lose their motility, and potentially motile bacteria may be motile when cultivated at one temperature but not at another. The inclusion of antibacterial substances such as phenol in the medium in toxic but non-lethal concentrations inhibits the formation of flagella by bacilli of the *Salmonella* group, in fact, one method of obtaining these forms free from flagella and the antigenic substances associated with them is culture on nutrient agar containing 0.1 per cent phenol.

Spores. The spore is a consequence of the aggregation of cell substance within a spore case during spore formation. It is this process rather than the formation of a structure of the vegetative cell that is subject to variation. Like capsule formation it is essentially a physiological process but with morphological consequences. Spore formation is affected by environmental factors, and asporogenous variants which breed true also occur. In the case of the anthrax bacillus, for example, spores are formed only when the bacteria have access to free oxygen, only vegetative forms are found in the infected animal until the bacilli are exposed to air by tissue decomposition or autopsy and then spore formation occurs. Similarly, spores are formed most rapidly at 32° C., less so at 37° C., and not at all when the culture is incubated at 42° C. The inhibition of spore formation by the anthrax bacillus by high temperatures is a temporary one in that when the temperature of incubation is reduced spore formation again occurs, but if cultures are maintained at 42° C. for many transfers the ability to form spores is apparently permanently lost. In general, however, spore formation is a relatively stable character.

Involution Forms. The occurrence of aberrant or "abnormal" forms of bacteria is very common and observed most frequently in old cultures. As indicated earlier (p. 40), such forms are commonly regarded as involution

forms, that is to say, dead or dying cells, and it has been pointed out that the physical structure of dead bacteria breaks down, with the protoplasm becoming granular and escaping into the surrounding medium with disintegration of the cell wall (Fig. 5). In addition to such dead cells, filamentous and coccoid forms of bacilli, swollen cocci, and the like are found with some frequency.

The tendency to aberrant morphology is in part a function of the structural rigidity of the bacterial cell, and in part an effect of the environment on the cell. It is self-evident that this should be so in a macromolecular environment; for example, no small degree of structural rigidity is necessary to maintain a bacillary form in the face of the forces of surface tension, and any crumbling of that structure will of necessity result in misshapen cells.

Fig. 26. Involution forms of the typhoid bacillus; fuchsin stain. Note the filamentous forms and elongated rods mixed with the typical forms. What appear to be buds on the filament are probably adjacent cells. The poor resolution at these high magnifications is apparent. $\times 3500$.

Thus, the non-sporulating anaerobic bacilli (p. 540) and the pleuropneumonia-like organisms (p. 547) are perhaps the most fragile of all bacteria, and in keeping with this have a highly variable morphology. Similarly, the cholera vibrio is a fragile bacterium, easily broken up by grinding procedures, and is notorious for its morphological instability.

In old cultures accumulated metabolic products not only affect the viability and reproduction of cells, but may well contribute more directly to the development of aberrant forms. Morphological variation may be produced experimentally by manipulation of the medium. If, for example, surface tension is lowered by the inclusion of a surface tension depressant, aberrant morphology results, and among the bacilli the rod form becomes elongated to give rise to filaments. Analogous effects are produced by the cultivation of bacteria in the presence of toxic but not lethal concentrations of salt. Another kind of effect is produced by the inclusion of antibiotic agents which inhibit cell division; the cells continue to metabolize but fail to divide, and assume swollen, misshapen forms.

It will be clear from the foregoing that a large proportion of morphologic-

ally abnormal bacterial cells are to be found in old cultures which arise as a consequence of the toxicity of accumulated metabolic products, and the disintegration of the structure of dead and dying cells. It is not so clear to what extent essentially normal physiological activity and ability to reproduce are associated with the structural integrity of the cell. Certainly some degree of distortion is not fatal, for example, the filamentous forms of bacilli produced by depression of surface tension of the medium are viable in many cases. It seems probable, however, that the physical organization of the cell is of no small importance, and in this connection it is significant that cultural studies of the aberrant forms found in old cultures have indicated that in the great majority of instances these forms are dead in that they are incapable of multiplication. A part, perhaps a very large part, then, of variation in the morphology of the bacterial cell is no more than the outward evidence of a dying population and the death and disintegration of individual cells.

Bacterial Life Cycles. Cyclical development of bacteria in a succession of morphological types is well known in some cases. The simplest is the spore-vegetative cell succession of the sporulating bacteria. The succession of morphological types, or cytomorphosis (p. 59), associated with the growth of the bacterial population discussed earlier, and the successive zoogeal and monad or swarmer stages of *Nitrobacter* also seem well established. Considerably more complex developmental cycles, or cyclogenies, analogous to those well known among the fungi and higher plants, have been postulated by some workers for many of the well-known bacteria such as the staphylococci, streptococci, enteric bacilli and the like.

The experimental evidence upon which the belief in bacterial life cycles is based consists of observations of aberrant, "abnormal" forms occurring in pure cultures. It is postulated that the so-called "normal" bacterial form is but one morphological stage of many in which a bacterium may exist but in which it is temporarily fixed by the constant environment of the laboratory medium. The appearance of aberrant forms is, then, evidence of a tendency on the part of the organism to assume the forms characterizing other stages of the life cycle, and such forms should not be termed involution or degenerative forms. The aberrant cells in turn break down to liberate minute viable organisms either directly or via a symplastic stage. The minute forms, designated as gonidia, gametes, microgametes and the like, may give rise to the "normal" vegetative cell, either directly or after a process of conjugation or sexual union.

In any attempt to weigh the evidence in favor of bacterial life cycles two points must be borne in mind. In the first place, the aberrant forms which constitute an essential part of the life cycle occur only in the death phase of a bacterial culture, never during the phases of active growth; and, in the second, many of the postulated forms are too small to permit resolution with visible light. Alternative explanations of aberrant morphology are many. Suppose the cell dies, autolysis follows with the breakdown of cell constituents to smaller molecules, the increase in the number of molecules in solution raises the osmotic pressure within the cell and the cell imbibes water with resultant distention and eventual disruption. Granular material may be volutin and similar granular substances commonly observed in bacterial cells.

It is perhaps significant that studies utilizing the micro motion picture tech-

nique for the continuous observation of the development of bacteria from a single cell have yielded no evidence of a bacterial life cycle.⁴ The evidence for the existence of such life cycles is exceedingly tenuous for two reasons. Much of it is open to serious technical criticism,⁵ and in all cases there are equally plausible alternative explanations. Aside, then, from the point of technical criticism, differences in opinion are largely a matter of interpretation and, in the absence of conclusive experimental evidence, which has as yet not been forthcoming, are likely to remain so for the time being.

Filterable Forms of Bacteria.⁶ Perhaps associated with bacterial life cycles are the so-called filterable forms of these organisms. The visible, readily cultivable forms of bacteria such as are present in the ordinary "pure culture" do not usually pass through the finer-pored porcelain and infusorial earth filters. That there are particular conditions, however, that favor the transmissibility of certain bacteria through these filters has become increasingly evident. Aside from the technical difficulties that beset all filtration experiments there are serious divergences of interpretation. Many observers have reported that familiar microorganisms such as the tubercle bacillus and the typhoid bacillus can sometimes pass through well constructed filters and this they interpret as signifying the existence of a filterable stage in the life history of these bacteria. It is even alleged by some that the filterable viruses of smallpox, poliomyelitis and other diseases represent a filterable phase in the life cycle of visible microorganisms, streptococci or what not, a view that has been urged especially by Rosenow⁷ in this country and Enderlein⁸ in Europe. This view is by no means generally accepted.

On the other hand, it is maintained that the so-called "filterable" forms of the typhoid bacillus, for example, are merely cells dwarfed by inadequate nutrition or are viable cell particles so small as to pass through filters but with capacity of renewed growth when again placed in favorable surroundings. It may be urged that the ability of cell fragments to regenerate is no new thing in biology, and it is quite as plausible to regard minute filterable forms of cocci or tubercle bacilli as portions of fragmented cells as to look on them as representing a significant filterable phase in their life histories.

PHYSIOLOGICAL VARIATION

Variation in the physiological activities of bacteria is exceedingly common. It may take various forms such as alterations in virulence, *i.e.*, ability to produce disease, changes in fermentative activity and nutritive requirements, or the acquisition of resistance to antibacterial agents.

Attenuation. The term attenuation is ordinarily loosely used to mean reduced virulence of a pathogenic microorganism. It may indicate a simple loss of ability to produce disease in a general sense, or a reduction in virulence for one host species accompanied by an increase in virulence for another host species.

In general most pathogenic bacteria tend to lose virulence when kept in culture on artificial media. For example, pneumococci rapidly lose virulence for the mouse and in even a very few transfers on enriched media the minimal lethal dose increases by several hundred fold. Staphylococci, however, retain their virulence over many transplants on artificial media, but eventually become relatively avirulent. A few bacteria, such as the anthrax bacillus, seem to retain virulence almost indefinitely but this is not common. Such losses in virulence are general in character in that the bacteria become less virulent for a variety of experimental animals, and presumably arise as a consequence of adaptation to an environment other than that of the animal body. The artificial environment may be deliberately made somewhat toxic in order to bring about such changes. Simple aging in the case of Pasteur's cultures of the fowl cholera organism was sufficient to reduce virulence so that a fatal infection was not produced, and the attenuated strain of bovine tubercle bacillus known as BCG was carried on a bile-containing medium until its virulence was apparently completely lost.

Loss of virulence may be accompanied by changes in other characteristics such as marked diminution in capsule formation by the pneumococcus, a loss of golden pigment by *Staphylococcus aureus*, somewhat less fastidious nutritive requirements, etc. In many instances the change is dissociative in nature and loss in virulence is associated with a shift from the smooth form. In most bacteria, of course, virulence is markedly reduced by the S-R dissociation, and a change of this kind may occur *in vivo*, presumably under the influence of antibody; for example, the typhoid bacilli excreted by most chronic carriers are rough, avirulent forms.

Virulence may often be restored by animal passage, e.g., successive and repeated infection and reisolation of the bacterium through a series of experimental animals. It cannot be concluded that the microorganisms are individually altered in the restoration of virulence by animal passage, and it is more probable that the animal acts as a highly selective screen, separating out those few bacteria in the inoculum which multiply most rapidly in the tissues. The restoration of virulence is usually accompanied by a restoration of other characters associated with it such as capsule formation.

The virulence of a microorganism may be modified by passage through another host species and sometimes, though not invariably, virulence for the original host species is reduced. The classic example of attenuation by animal passage is that of Pasteur's attenuation of the rabies virus by adaptation to the rabbit brain. The original strain from dogs, "street virus," kills rabbits in about two weeks following subdural inoculation, after some twenty passages it kills in eight days, and after an additional twenty or more passages the period may be reduced to seven days but cannot be reduced further. This "fixed virus" has acquired such a marked affinity for the nervous tissue that it will not produce rabies on subcutaneous inoculation and so may be used as an immunizing agent. Such attenuation or adaptation to a new host is very common among the viruses, and includes the adaptation of a variety of viruses to the chick embryo, the adaptation of yellow fever virus to the mouse brain, etc. Perhaps the best known single example is that of the conversion of smallpox virus to cowpox virus.

Attenuation of virulence is of considerable practical importance in relation to the preparation of immunizing agents. Among the bacterial diseases, killed vaccines are not effective immunizing agents in anthrax and tuberculosis, but attenuated anthrax bacilli were originally used by Pasteur to immunize sheep, and the attenuated strain of tubercle bacilli, BCG, has been of increasing interest as an immunizing agent in man. Among the virus diseases, effective immunity is rarely obtained with killed material, and vaccines of attenuated virus, often given in conjunction with antiserum, are very valuable.

Biochemical Variation. Variation in the biochemical properties of bacteria, such as fermentation of sugars, decomposition of proteins and amino acids, nutritional requirements, resistance to antibacterial agents, and the like occurs with some frequency. Changes may appear seemingly spontaneously, but more often seem to be in the nature of an adaptive response to the environment.

Fig. 27 Colonies of *Bact. coli mutabile* on lactose agar. Note the lactose-fermenting papillae of the variant appearing on the non-lactose-fermenting colonies (Parr).

Mutation-like Variation. The best known example of variation of this kind was first observed by Massini in 1907. He isolated a non-lactose-fermenting strain of *Bacterium coli* which, when cultivated on lactose agar containing an indicator which turned red in the presence of acid, gave rise to white colonies. On continued incubation, however, red papillae appeared on the colonies, indicating that some of the bacteria were decomposing the sugar to acids. This is illustrated in Fig. 27. Subcultures from the red papillae bred true and showed no tendency to revert to the non-lactose-fermenting form, while subcultures from the white portions of the colonies gave rise to white colonies on which red papillae appeared as before. He concluded that the change was a mutation and that some strains of the colon bacillus, which he named *Bacterium coli mutabile*, were genetically unstable with a tendency to throw off lactose-forming mutants. Such strains of colon bacilli have since been found repeatedly and the variation has been studied in some detail. It was found by Lewis⁹ that if such strains were cultured on a synthetic medium containing lactose as the only source of organic carbon, a constant proportion,

⁹ Lewis Jour. Bact., 1934, 28 619.

Further light has been thrown on the probable nature of the anti-opsonic substances in aggressive exudates during the prolonged and detailed study of the factors involved in antipneumococcal immunity.

Rosenow (1907) described extracts and autolysates of virulent pneumococci which inhibited the phagocytosis of relatively avirulent pneumococci; he suggested the name *virulins* for the active substances concerned.

Cole (1917) observed that empyema fluids from pneumococcal infections contained soluble substances which specifically neutralized the protective antibodies in an antipneumococcal serum, and that similar substances might be present in the blood of rabbits suffering from experimental pneumococcal infection. He showed that, when an antipneumococcal serum was injected intravenously into a rabbit previously infected with the same type of pneumococcus, the protective antibodies disappeared very rapidly from the blood, and that a similar phenomenon could be demonstrated in patients severely ill with lobar pneumonia.

More recent studies on the antigenic components of bacterial cells (Chapter 8), and the demonstration that sensitization to the phagocytic action of polymorphonuclear cells and macrophages depends upon the union of antibody with an antigenic component situated at the surface of the bacterial cell, suggest that the substances responsible for the specific anti-opsonic effects of aggressive exudates are dissolved bacterial antigens. Landsteiner's demonstration of the inhibition of antigen-antibody reactions by simple haptens (see p. 297), and the *in vitro* reactions of specific bacterial polysaccharides that fail to stimulate antibody production *in vivo*, indicate that bacterial haptens, as well as complete antigens, may be expected to exert this anti-opsonic effect.

There is good evidence that this is actually the case. Sia (1926) has studied the action of the type-specific polysaccharides of Type II and Type III pneumococci on the growth of these organisms in serum-leucocyte mixtures from the rabbit and from the cat. The pneumococci were of relatively low virulence and developed very poorly in both the serum-leucocyte mixtures employed. The addition of minute amounts of Type II polysaccharide greatly increased the growth of Type II pneumococci, but had little effect on the growth of the Type III organisms. The addition of minute amounts of Type III polysaccharide greatly increased the growth of Type III pneumococci, but not of Type II.

Felton and Bailey (1926) also demonstrated the aggressive action of Type II polysaccharide, by injecting it into mice, together with relatively avirulent pneumococci of the same type, and inducing a fatal infection. Type I polysaccharide had analogous effects (Ward 1930), and the anti-bactericidal effect proved to be due to the specific inhibition of phagocytosis (Ward and Enders 1933). The anti-phagocytic action of the Type I polysaccharide as prepared in the laboratory was not so pronounced as that of Type II and Type III polysaccharides. Nor was it as pronounced as that of extracts of pneumonic lungs infected with Type I pneumococcus (Ward 1932). The discrepancy was later resolved by the discovery that the polysaccharide preparations, unlike native polysaccharide, were not acetylated (see Chapter 8). Acetyl polysaccharide proved to be fully anti-opsonic (Enders and Wu 1934). The aggressive effect of the pneumococcal polysaccharide in human infections is suggested by the work of Cole (1917) and Park and Cooper (1928), who record that a fatal outcome in cases of lobar pneumonia in man is frequently associated with the presence in the blood of specific soluble antigen in amounts greater than can be neutralized by the antibodies that the patient has produced.

Downie (1937) observed an aggressin-like effect of Type I pneumococcal polysaccharide. Mice immunized with a single dose of polysaccharide were resistant to a given dose of Type I pneumococci. When this dose was injected together with 0.05 mgm. of the same polysaccharide, the immunity was in most cases abolished. Nye and Harris

about one in 100,000, of the cells were able to grow. Further studies by Deere¹⁰ have shown that both fermenting and non-fermenting varieties contain the enzymes necessary for the lactose fermentation, and suggested that the fermenting variants differ from the parent strain in that the cell wall is permeable to lactose.

A similar mutation-like change with respect to citrate utilization by coliform bacteria has been observed by Parr and Simpson,¹¹ and extensive experiments with other members of the colon-typhoid-dysentery group of bacilli have shown that this kind of variation with respect to the fermentation of other substances such as dulcitol is not uncommon. A number of these organisms will, when cultivated on media containing a sugar they are unable to ferment, respond with the formation of such papillae, the tendency toward reversion to the parent type varying from one organism to another.

Mutation-like variation occurs in properties other than sugar fermentation. One of the most adequately studied of these is pigment production by *Bacterium prodigiosum*, which has been investigated by a number of workers, especially Bunting.¹² During growth of the culture white, pale pink, bright pink and dark red variants are thrown off at a relatively constant rate, one per 10,000 cells in the case of dark red and one per 3000 cells in that of bright pink, but, with rare exceptions in the case of white and pale pink, these variants do not breed true and on subculture show essentially the same color distribution as the parent strain.

Variation by Adaptation or Training. Changes in biochemical properties also occur in a seemingly more gradual way, induced by continued cultivation in appropriate media. Such variation in nutritive requirements is the basis for the general observation that the more fastidious pathogenic bacteria are frequently more difficult to cultivate on primary isolation and enriched media are required, while, after being carried in culture for some time, they grow more rapidly and profusely and on somewhat simpler media. For example, on primary isolation *Brucella abortus* requires an increased carbon dioxide tension, but after a few subcultures this may be dispensed with. Similarly, the gonococcus and meningococcus require, on primary isolation, both an increased carbon dioxide tension and an enriched medium, usually a heated blood medium. After a few subcultures, however, it is no longer necessary to supply carbon dioxide, and eventually growth occurs in simpler media.

This process of adaptation to growth on an originally deficient medium has been studied with respect to specific nutritional requirements. Fildes, Gladstone and Knight¹³ found, for example, that some strains of the typhoid bacillus which require tryptophane could be trained to grow without this amino acid by successive culture in decreasing concentrations of it. Gladstone¹⁴ similarly showed that some strains of *Staphylococcus aureus* that initially required a number of amino acids could eventually be adapted to grow in the presence of an ammonium salt as the only source of nitrogen, and

Koser and Wright¹⁵ could adapt dysentery bacilli requiring nicotinic acid to growth in its absence. Ability to ferment carbohydrates may also be either acquired or markedly enhanced by continued cultivation in the presence of the substrate or by very heavy inoculation of highly specific media in which the substrate is the only nutritive material. Still other adaptations such as to changes in pH, increased incubation temperature and the like also occur, but are usually not marked.

*Adaptive Enzymes.*¹⁶ The ability of a microorganism to decompose a substrate may be very rapidly enhanced in the presence of that substrate. Although known for many years, this particular kind of bacterial variation has been the subject of renewed interest as *enzyme adaptation*. The enzymes which may be formed under the influence of the presence of substrate have been called adaptive enzymes in contrast with those which are formed whether or not the substrate is present, the constitutive enzymes. The formation of adaptive enzymes may be demonstrated by cultivation of the bacteria in a medium containing the substrate and then testing the organisms for enzymatic activity, or a washed suspension of bacteria grown in the absence of the substrate may be mixed and incubated with it. In the first instance, activity is immediately apparent, the bacteria having formed the adaptive enzyme during growth, and in the second a latent period varying from thirty minutes to two to four hours occurs before rapid decomposition of the substrate begins.

Thus, washed suspensions of the colon bacillus bring about an equally rapid decomposition of glucose, as measured by oxygen uptake in respirometers, regardless of whether the medium upon which the organisms were grown contained this sugar. On the other hand, the enzyme system of this organism which is responsible for the decomposition of tryptophane to indol is an adaptive enzyme. If the medium upon which they are grown contained tryptophane, washed suspensions immediately convert the amino acid to indol, but if the medium did not contain tryptophane and the washed bacilli are suspended in tryptophane solution, decomposition to indol occurs only after a latent period. Similarly, the amino acid decarboxylases are formed for the most part in the presence of the substrates. Many of the bacterial proteases are adaptive enzymes, for only small amounts of the enzymes are formed in the absence of protein, but filtrates from cultures in protein-containing media are actively proteolytic. Various other bacterial enzymes are adaptive also, thus, the enzyme responsible for the reduction of tetrathionate to thiosulfate by *Salmonella paratyphi* B, tetrathionase, and that catalyzing the reduction of nitrate to nitrite by *Bact. coli*, nitratase, are adaptive.

The question of whether or not the formation of an adaptive enzyme is associated with bacterial multiplication is one of considerable interest. In general it appears that some degree of multiplication is essential (cell division occurs even in suspensions of washed bacteria), and it has been shown in the formation of galactozymase by *Bact. coli* that the amount of enzyme was proportional to the number of new cells.¹⁷ In a few instances, however, adaptive

Note.—For species of *Salmonella* not given in this list, see pp. 823-848

enzymes have been found to be formed by washed bacteria in the presence of the substrate and under circumstances in which there was no detectable cell division; these include the formic hydrogenylase of *Bact. coli*,¹⁸ the galactozymase of *Saccharomyces cerevisiae*¹⁹ and the nitratase and tetrathionase of *Salmonella paratyphi* B and *Bact. coli*.²⁰ The formation of adaptive enzymes by partially poisoned bacteria, i.e., those which cannot reproduce but continue to metabolize, has, however, not been observed.

The distinction between adaptive and constitutive enzymes is not a sharp one, for frequently, as in the case of the bacterial proteases, the adaptive enzyme is not completely lacking in the absence of the substrate. It is clear that there is some relation between the formation of adaptive enzymes and adaptation to a substrate by serial culture in its presence in that the distinction appears to be in part a quantitative one. In bacterial growth enzyme adaptation is expressed in terms of the lag period and the generation time during the period of active growth. What might be called the population-growth expression of adaptive processes has been studied at some length by Hinshelwood and his colleagues.²¹ They have shown that, in the adaptation of *Bact. aerogenes* to the most efficient utilization of substrates such as glycerol, disaccharides, glycine, etc., the adaptation is expressed as a transition from a slower to a more rapid rate of growth in the early stages as indicated by breaks in the growth curves, and as a decrease in mean generation time in the period of logarithmic growth, the latter decreasing from 70 to 110 minutes for unadapted strains to 32 to 33 minutes for adapted ones. The process of adaptation cannot be fully explained, however, on the basis of rate of formation of adaptive enzymes, for an adaptive enzyme, such as a bacterial protease, does not tend to persist as a constitutive enzyme when the bacterium is kept on protein-containing media for many transfers and then cultured in the absence of protein. An adapted strain tends to breed true to a certain extent in that there is a tendency for the acquired property to persist in the absence of the substrate, and the tendency is directly related to the extent to which adaptation is carried. Strains of bacteria vary, but in a general sense it might be said that following fifteen transfers in substrate-containing media, the property tends to disappear at about the same rate as that at which it was acquired, but if the process of adaptation has been carried on for, say thirty transfers, it may persist indefinitely in the absence of substrate.

Drug-Fastness. Microorganisms may become adapted to the action of antibacterial substances, and by a process of training acquire the ability to grow in concentrations that are bacteriostatic for the unadapted parent strain. This adaptation is of particular interest in relation to the antibacterial agents of chemotherapeutic importance, including certain of the dyes, the sulfonamide compounds, and the antibiotics, penicillin and streptomycin in particular. Such adaptation occurs readily *in vitro* when the microorganisms are grown in increasing concentrations of the antibacterial agent, and there is convincing

evidence that it also occurs *in vivo* though the relative importance of the latter phenomenon is not altogether clear. Strains of pathogenic microorganisms that have become resistant to the action of antibacterial substances in concentrations within a chemotherapeutic range are said to be drug-fast.

From a practical point of view it is significant that such adaptation can occur *in vivo*. Chemotherapy of the parasitic infections, such as trypanosomiasis, is of long standing and the acquisition of drug-fastness by such parasites is well known. Similarly, the development of strains of *Treponema pallidum* which are drug-fast to the arsenicals is observed from time to time. The occurrence of drug-fast strains of bacteria has assumed importance with the advent and general use of antibacterial agents effective in the chemotherapy of bacterial infections, first the sulfonamides and later the antibiotics. For example, a striking increase in the proportion of drug-fast gonococci occurred with the general application of sulfonamide therapy of gonorrhea. Carpenter *et al.*²² observed an increase in the incidence of sulfonamide-fast strains of the gonococcus from 15 to 59 per cent in a period of fifteen months; similar results have been reported from Britain, and it is a common observation that at the present time the majority of cases of gonorrhea do not respond to sulfonamide therapy.

The prophylactic use of chemotherapeutic drugs also results in the development of drug-fast strains of bacteria. Thus, Siegal, Karr and Julianelle²³ found that sulfadiazine prophylaxis produced drug-fast pneumococci which spread, infecting some 90 per cent of the group under observation, and the institution of sulfadiazine prophylaxis of streptococcal infection in naval training camps in the United States during World War II was followed by a tremendous proportionate increase in drug-fast strains of streptococci within these groups which produced streptococcal infections that did not respond to sulfonamide therapy (p. 359). Cases of infection with sulfonamide-fast pneumococci have been found and the development of drug-fast strains during therapy and their spread to other persons have been observed; as yet, however, no widespread prevalence of infection with sulfonamide-fast pneumococci has been observed, and according to Hamburger *et al.*²⁴ the occurrence of drug-fast strains has not been quantitatively important in clinical practice as yet.

The widespread use of penicillin has resulted in an increase in penicillin-fast strains of staphylococci; in Hammersmith Hospital in London 14.1 per cent of strains isolated from lesions in the period April–November, 1946, were penicillin-fast, and this rose to 38 per cent for the period February–June, 1947.²⁵ Drug-fastness to streptomycin is especially prone to occur, and develops so rapidly in the infected individual undergoing therapy as to limit somewhat its chemotherapeutic value. It is not clear whether the observed increasing proportion of drug-fast strains of bacteria results from an adaptation to the drug *in vivo* and spread of the fast strain, or whether the drug-

fast strains exist prior to therapy and occur in larger proportion through elimination of susceptible strains by chemotherapy. It is not unlikely that both processes are operative, but their relative importance is not known. In any case it is clear that virulent, drug-fast strains of bacteria can and do develop and become disseminated through the host population.

As indicated elsewhere (p. 155), antibacterial agents affect the physiological processes of the cell, and it follows that the nature of the modification that results in drug-fastness is essentially one in the physiology of the bacterium. There is evidence for three general kinds of modification, viz.:

(1) If the drug acts by interference with some particular metabolic process, it is not unreasonable to suppose that the drug-fast strain may by-pass that process and make use of some alternative mechanism. If so it might be expected that the fast strain would differ physiologically from the parent strain. Such physiological differences have, in fact, been observed in sulfa-pyridine-fast pneumococci which, while dehydrogenating glucose at a rate equal to that of the parent strain, cannot dehydrogenate 3-carbon intermediates such as glycerol, lactate and pyruvate, while the parent strain can, and show also a marked diminution in hydrogen peroxide production.²⁶ If, however, the drug interferes with a synthetic process, the modification would not appear in the respiratory metabolism. While the processes of synthesis are much less well understood, there is evidence which suggests that alternative pathways of synthesis may be developed, as in the syntheses involving pantothenic acid catalysis by streptococci²⁷ and pantothenic acid and tryptophane metabolism of staphylococci.²⁸

(2) Since the action of the sulfonamides is antagonized by *p*-aminobenzoic acid, it has been suggested that in some instances sulfonamide-fast strains of bacteria are resistant by virtue of an increased production of this or similar antagonists. In support of this it has been found that sulfonamide-fastness of staphylococci and gonococci is in some cases associated with the production of increased amounts of *p*-aminobenzoic acid,²⁹ and it has also been shown that pantolyltaurine-fast strains of the diphtheria bacillus are resistant because of their ability to synthesize pantothenic acid.²⁷ Specific antagonists of many antibacterial substances, including the antibiotics, are not known and the extent to which this general explanation of drug-fastness can be tested is not great as yet.

(3) A third possible explanation is that, if the drug acts as a competitive inhibitor of an essential metabolite because of similarity in molecular structure, the adaptation may consist in the development of the ability to metabolize the drug instead of the metabolite, giving rise to an apparently anomalous situation in which the essential metabolite shows antibacterial activity. A number of observations in support of this view have been reported. It was found by Wooley³⁰ that strains of the yeast *Endomyces vernalis* which were inhibited by pyriithamine, an analogue of thiamine, could be made resistant

by cultivation in its presence, and simultaneously acquired the ability to utilize pyriithiamine instead of thiamine. Emerson and Cushing³¹ reported that a strain of the fungus *Neurospora*, made sulfonamide-fast by cultivation in the presence of sulfanilamide, not only utilized the drug but required it as an essential metabolite, and that the drug-fast strain was inhibited by *p*-aminobenzoic acid, the reverse of the behavior of the parent strain. Similarly, streptomycin-fast variants of meningococci were found by Miller and Bohnhoff,³² some of which required streptomycin for growth, *i.e.*, were streptomycin-dependent, and others were only streptomycin-fast. Streptomycin-fast dependent variants of staphylococci, enteric bacilli, etc., have been described by Kushnik *et al.*³³ and by Paine and Finland.³⁴ The role of streptomycin as an essential metabolite for such variants is also strongly supported by the studies of Rake.³⁵

There are, of course, still other explanations of the basis of adaptive resistance to antibacterial agents. For example, a degree of tolerance might also result from the development within the cell of substances which decrease the solubility of the drug and hence its ability to penetrate the cell; such an explanation has, in fact, been suggested to account for the tolerance which certain fungi may develop for disinfectants. Or the drug-fast variant may inactivate the antibacterial agent by decomposition; naturally occurring penicillin-resistant strains of staphylococci often produce penicillinase, and penicillin-inactivating substance is formed by some penicillin-fast variants.³⁶

It is not necessary to assume that a single mechanism is operative in the development of drug-fastness, *i.e.*, those indicated above are in no sense mutually exclusive, and it is, in fact, probable that a variety are functional. For instance, while sulfonamide-fastness of gonococci is sometimes associated with an increased production of *p*-aminobenzoic acid as noted above, all sulfonamide-fast gonococci do not produce antagonists. Furthermore, more than one mechanism may be operative in a single adaptation; Davies and Hinshelwood³⁷ have reported, for example, that in the adaptation of *Bact. aerogenes* to sulfanilamide there is first a reduction in the prolonged lag period produced by the drug which they interpreted as the development of an alternative growth mechanism, and later an enhanced growth rate due to the formation of an antagonist.

The development of drug-fastness is most commonly a gradual process, though there are exceptions such as the streptomycin-fast dependent meningococci which appear on initial culture. The bacteria are usually cultured in increasing concentrations of the drug over an extended series of transplants and become more and more drug-fast in that successively higher concentrations are tolerated. These sometimes become almost fantastic in the light of the original sensitivity. The drug-fastness is specific also in that a sulfonamide-fast strain is normally susceptible to penicillin, etc. This specificity may

extend within a group of closely related compounds such as the sulfonamides, and Harris and Kohn³⁸ have reported that acquired resistance of *Bact. coli* to sulfanilamide did not always parallel that to sulfathiazole. Or it may extend to other compounds; thus Hinshelwood²¹ has shown that *Bact. aerogenes* adapted to proflavine shows some "cross adaptation" to other acridines, methylene blue, and propamidine. In general, the specificity is greatest in the early phases of the adaptation. As indicated above, drug-fastness may be temporary in that reversion occurs on continued culture in the absence of the drug, but when the adaptation is carried over many transplants and to relatively high concentrations of the drug, it is apparently permanent. Reversion may be induced in some instances, however, by adaptation to some other drug, and acriflavine-fast *Bact. aerogenes* becomes susceptible to acriflavine when adapted to phenol.

Immunological Variation. The loss of capsules in the conversion of S to R forms is reflected, not only in the morphology and virulence of the organism, but also in its immunological character. The capsular material, usually polysaccharide in nature, confers a type specificity upon the organism, while the cell body proper contains antigens, designated as somatic, which confer an immunological relation upon closely related forms having similar or identical somatic antigens but different type-specific antigens. The change from S to R is, then, ordinarily accompanied by a loss of immunological specificity. The pneumococcus types, for example, differ from one another by virtue of type-specific capsular material and in the rough form lose their type specificity and become immunologically identical (p. 385).

Another type of colony variation or dissociation connected with the presence or absence of flagella was originally observed in cultures of *Proteus vulgaris*. The ordinary type of *Proteus* colony is irregular and tends to spread in a thin film over the surface of an agar medium because of the pronounced motility of these organisms, but occasionally compact, discrete colonies are observed. The spreading type has been designated by the letter H (German *Hauch* = film) and the discrete form by the letter O (German *ohne Hauch* = without film). The distinction between H and O forms has come to have considerable significance because of the difference in the antigens present in the flagella and those present in the cell body, the H or flagellar antigens conferring, like the capsular polysaccharide of some organisms, a type specificity upon the bacterium. The O antigens, though often referred to as somatic antigens, are by no means strictly analogous to the somatic antigens of the rough forms of bacteria, as will appear.

The nature of the H-O variation would appear to be different from that of the S-R variation in that the former takes place somewhat more readily and does not have a semipermanent character. The formation of flagellar antigen, for example, may be suppressed by cultivation of the bacteria on phenol agar, a suppression which is immediate but not permanent, for transfer to nutrient agar results in the prompt reappearance of the H antigens. Furthermore, the H antigens of *Salmonella* have been found to be of two kinds, specific and non specific (the non-specific having even broader group affiliations than the O antigens). Bacterial species having both specific and

the cyclical processes of carbohydrate metabolism like the alcoholic fermentation, the Krebs cycle, etc. The individual reactions are determined by the concentration of intermediates, the amount of enzyme and the reaction velocity. A steady state occurs during logarithmic growth, but with the exhaustion of food materials, accumulation of metabolic products and the like, there is cessation of the maximum growth rate and concentrations of diffusible intermediates fall, and the individual enzymes decay and alter in their relative proportions as the system moves toward a new equilibrium. On transfer to fresh medium readjustment occurs.

toward an equilibrium consistent with maximum growth rate. Thus, the relative proportions of the elements of the catalytic system and the concentrations of substrates of the individual reactions exist in a series of metastable states of enzyme balance under ordinary culture conditions. For example, the formation of bacterial deaminases is suppressed during rapid growth in the presence of fermentable carbohydrate and does not occur at acid reactions but decarboxylases are formed at an acid reaction, and both kinds of enzymes are formed in the later stages of culture growth; the kind and proportion of enzymes present is a function of the age and condition of the culture. Similarly, the products of carbohydrate metabolism depend upon environmental factors, again a matter of balance in the function of the cellular enzymes.

If a strain of bacteria is transplanted to a medium differing from the one in which it has been grown, a greater degree of adjustment occurs. For instance, *Bact. aerogenes* ferments both glucose and lactose, but if cultured continuously on glucose and then transferred to lactose, the growth rate, measured as the mean generation time, is reduced. After several transfers in lactose the rate increases and the strain grows as rapidly in lactose as it formerly did in sucrose. If the training to lactose is only partial, reversion occurs in non-lactose-containing media, but if the strain has been carried through many transplants in lactose, the ability to use the sugar with a maximum efficiency persists. Since the bacterium ferments both sugars with facility the adaptation is not overt, but it is, nevertheless, a typical adaptation, and the result is clearly a consequence of alteration in the balance of enzymes already existing in the cell. The adaptive process is much more striking, and less obviously a result of change in enzyme balance, when there is a great differential between the parent and adapted strains, as between no detectable acidity and an active fermentation, whether it occurs slowly on successive transfer or very rapidly as in the formation of an adaptive enzyme.

The change in enzyme balance may be quantitative in nature. The enzyme in question may be present only as a precursor, the formation of enzyme occurring in the presence of substrate through mass action as suggested by Yudkin⁴⁹ for adaptive enzyme formation. Or the enzyme may be initially present in only very small amount, on the basis of comparison between number of molecules of certain vitamins per cell and the turnover rate of several enzymes, McIlwain⁵⁰ indicates how some enzymes may be present as only one or a few molecules. Or, finally, catalysis of the new reaction may be a function of an

⁴⁹ Yudkin Biol. Rev., 1938, 13:93.

⁵⁰ McIlwain Nature, 1946, 158:898.

existing enzyme but at a relatively low reaction velocity, and adaptation a matter of expansion of that enzyme. The last opens the question of qualitative modification of the enzyme, in that distortion of its specificity by a slightly different substrate requires greater activation energy and hence a lowered reaction rate, but if the substrate is present during formation of the enzyme, and the distortion not too great, a modified pattern may eventually result. This is consistent with much of the observed data but there is no direct evidence regarding it.

Drug-fastness is also satisfactorily explained in terms of enzyme balance. As indicated earlier, drug-fastness may result from the production of an inhibitor such as *p*-aminobenzoic acid in excess amounts, a qualitative modification such that the drug displaces the antagonist as an essential metabolite, or by diversion to an alternate metabolic pathway. The first of these is clearly an expansion of an existing catalytic system. Regarding the second, suppose it be assumed that the drug displaces the prosthetic group of an enzyme, *viz.*, panto-lyltaurine, to give a modified enzyme and the formation of different metabolic products. The adaptation can thus consist of an altered enzyme balance to allow the metabolism of the new intermediates, and when this is established, the original essential metabolite competitively inhibits the new system and the drug has become an essential metabolite. The development of an alternate metabolic pathway is likewise an expansion of an existing enzyme or system of enzymes which ordinarily contributes in but small amount to the maintenance of the concentration of a given intermediate, perhaps because of lower reaction velocity. When the function of the usual system is inhibited by the drug, the alternate is expanded, perhaps only quantitatively, to neutralize the effects of the lower reaction velocity. The whole is analogous to an industrial system in which a raw material for a given process is shut off, an alternative, more expensive process is developed and the economies effected in large scale operation make it as efficient as the original process.

THE INTERPRETATION OF THE PHENOMENA OF VARIATION

The significance of the phenomena of bacterial variation to biology is uncertain. Because of unique environmental factors interpretation of the morphological variation of individual cells presents unusual difficulties, and neither the mechanisms underlying this type of variability nor its relation to variation in anatomical structures of higher organisms is apparent as yet. Variation in colonial morphology, however, appears to be associated, in part, with physiological and immunological variation, and it is not unlikely that changes in colony form arise as a consequence of alterations in the nature of the cell surface.

The significance of the apparent loss and gain of physiological characters, even if these be absolute in that a property is completely lost or absent, is difficult to assess in general biological terms. As Needham²¹ has pointed out, although a structure which makes possible a given physiological function may not be regained after being lost, the organism may re-acquire the function through the development of another and different structural mechanism. It is clearly open to question as to whether an enzyme system lost or gained by a

²¹ Needham: *Contributions of Chemical Physiology to the Problem of Reversibility in Evolution*. *Biol. Revs.*, 1938, 13:225.

bacterium may be regarded in the same category as an anatomical structure such as a tooth.

The immunological characters of bacteria, however, have their counterparts among the higher organisms in which immunological characters are known to be inherited, as in the case of human blood groups, or parallel phylogenetic relationships of accepted zoological classifications, as in the immunological relationship of blood proteins. In this connection it has been shown⁵² that the immunological character of serum proteins of pigeons is genetically determined. If immunological characters of bacteria are to be regarded as fundamentally significant, it appears that on the one hand bacteria are unstable in this respect, *viz.*, the constant fluctuation of specific and non-specific flagellar antigen in the diphasic *Salmonella*, and on the other, that such characters may be acquired through environmental influence. The fluctuating variation between specific and non-specific H antigens and the random redistribution of these antigens in the bacterial population following selection may well indicate, however, that some, at least, of these immunological characters may not be of fundamental biological importance, a suggestion that is, in part, supported by present knowledge of common antigens and partial antigens.

This apparent acquisition of new immunological characters is also of interest in a somewhat different connection, that of the apparent autocatalytic properties of some substances. Recent studies have indicated that some of the filterable viruses are proteins. Since these agents are able to increase in the body of the host, it would appear that they stimulate the host cells to form more virus protein. The analogy to the transmutation of pneumococcus types and the acquiring of the heterophile antigen by the typhoid and paratyphoid A bacilli is obvious.

Bacterial Phylogeny. From the evidence of comparative bacterial physiology (Chapter 4) it appears not unlikely that bacteria were among the first living organisms on the earth. The autotrophic bacteria may plausibly be regarded as primitive forms of life that could exist in an environment containing no organic matter, and that have persisted until the present time. Teleologically, it would seem that in the bacteria nature tried a variety of energy-yielding mechanisms ranging from the oxidation of inorganic compounds of nitrogen, carbon, sulfur, iron, manganese, etc., to the utilization of radiant energy by the photosynthetic forms. The last process, however, became of quantitative importance in the green plants rather than in the bacteria. With the accumulation of organic matter, transitional forms, persisting today as the facultative autotrophes, arose in which there appeared mechanisms for the oxidation of organic compounds, concurrent with this development came the ability to respire in the absence of molecular oxygen. The wide variety of bacteria which exist at the present time may well be regarded as a consequence of the physiological expansion made possible by the accumulation of a variety of organic compounds and the development of respiratory mechanisms that made possible their utilization. In this connection it is of interest that vestiges of autotrophic physiology, such as the ability to oxidize hydrogen, persist in some of the heterotrophic bacteria.

With this development of respiratory mechanisms, however, a series of de-

⁵² Cumley, Irwin and Cole *Proc. Nat. Acad. Sci.*, 1941, 27:565.

Hirst (1941) protected mice infected with Group C, but not those with Group A, by treatment with leech-extract hyaluronidase. Blundell (1942) found only a feeble protective action in bull-testicle hyaluronidase in Group A infections; and McClean (1942) none at all, in either Group A or C infections, with doses of enzyme in excess of those required for decapsulation of the streptococci *in vitro*. Kass and Seastone (1944), however, report that bull-testicle hyaluronidase increases the bactericidal power of normal blood for Group A streptococci, and will protect mice against Group A infection. (See also Rothbard 1948.)

It is possible that the Vi antigen of *Salm. typhi* (see Chapter 30), which is associated with the virulence of the organism, may act analogously to the capsular substances of the cocci. It is only one-fiftieth as toxic as the O endotoxin (Henderson and Morgan 1938); nevertheless, intravenous injection of extracts of Vi bacilli greatly reduces the protective effect of Vi antisera in mice infected with the living bacilli (Henderson 1939; see also Leon and Morales 1943). In animals with protective O antibodies, it is possible that the Vi antigen is an effective aggressin if it covers the surface of the infecting bacterium, thereby masking the O antigen and preventing opsonization by the O antibody (see Felix and Pitt 1951).

The "complete" antigens of enterobacteria, as extracted by the trichloroacetic acid method of Boivin, are both specifically and non-specifically aggressive (Boivin and Delaunay 1942, 1943, d'Alessandro 1951-52). The non-toxic polysaccharide hapten component of this lipo-protein-polysaccharide complex is also specifically aggressive, presumably because it neutralizes opsonic antibody (Boivin and Delaunay 1945). The non-specific effect of, for example, a *Bact. coli* complete antigen on a *Salm. typhi-murium* infection of mice, appears to be a consequence of intoxication of the experimental animal.

Aggressins of this kind are not confined to enterobacteria. Complexes isolated by the trichloroacetic acid method from virulent human tubercle bacilli will enhance the infectivity of tubercle bacilli for guinea-pigs, whereas similar extracts of attenuated strains do not (Raffell 1947).

The neutralization of protective antibody by soluble antigens is unlikely to have any general effect on infections of the non-immunized animal until antibodies are formed in response to the infection; and, as we noted in the last chapter, serum antibodies do not usually appear until the second or third day (see, e.g., Wood *et al.* 1946). Another action of antigens is possible, which may affect an earlier stage of the disease although we have no evidence as yet that it occurs, namely, the paralysis of antibody formation, either local or general, by overwhelming doses of antigen (see Felton 1949 and Chapter 50).

In addition to these dissolved haptens or antigens it is clear that some infective exudates will contain other more or less toxic substances of bacterial origin that interfere with the defence mechanism of the host, as we have already noted in anthrax infection. Both Pettersson (1940) and Stevenson and Reed (1940) record a negative chemiotactic effect in *Staph. aureus*; the substances responsible appeared to be distinct from the recognized components of staphylococcal toxin. Pettersson's substance, which he calls "negatactic," was antigenic, and antisera prepared against it had a protective effect in guinea-pigs and mice. Pettersson (1943) also described negatactic substances, distinct from capsular substances, in *B. anthracis* and pneumococci. The anthrax anti-negatactic sera appeared to act by permitting the infiltration into the infected tissue of active phagocytes. The pneumococcal negatactic substances displayed some degree of host-specificity; the phagocytes of man and of the rabbit were susceptible to its action, but those of the mouse and guinea-pig were not.

The frank toxins of a bacterium may have an undoubted specific action on the mesenchymatous defence cells of the host. Two pathogenic species, at least, *Staph. aureus* and *Str. pyogenes*, produce a specific leucocidin that attacks the polymorphonuclear cells, and, for example, Dennis and Senekjian (1939) report an antigenic leucocidin in *Salm typhi*. We know little as yet about the action of

generative changes appeared, the first being the loss of the ability to reduce carbon dioxide, followed by an increasing dependence upon preformed organic compounds as building stones for protoplasm and upon preformed components of the enzyme systems concerned in respiration, such as coenzyme, thiamine and the like. Degeneration appears most marked in the pathogenic forms (possibly reaching an ultimate in the filterable viruses if, as some think, these are microorganisms completely dependent upon the host cells for enzyme systems), and it is possible that this degeneration has been accelerated through parasitism.

Such an approach necessitates the assumption that the autotrophes appeared fully developed and in very many respects this seems highly improbable. An alternative which avoids this difficulty is the assumption that the formation of organic matter, through the condensation of small polyfunctional molecules with aggregation into macromolecules, preceded the appearance of living cells, and that these were essentially heterotrophic. From such heterotrophic ancestors the autotrophic bacteria could develop as the supply of preformed organic matter ran low, and present heterotrophic forms utilizing organic matter of green plant origin differentiated either from or coincidentally with the autotrophes.

Parasitism.⁵¹ Although the ability of some bacteria to produce disease may be a purely fortuitous coincidence, viz., the tetanus bacillus, many of the pathogenic forms have, through long association, become adapted to life in the body of the host to such a degree that they are unable to survive in nature or possibly even on artificial culture media or in the bodies of animals closely related to the particular host. This seems, for example, to be the case with the leprosy bacillus, which, so far as is known, is not able to grow anywhere except in the body of man and possibly of the anthropoid ape. Theobald Smith has suggested that bacteria of great pathogenic power should be regarded as incompletely adapted parasites that have not yet succeeded in establishing an equilibrium between themselves and their host. The less complete the adaptation, the more virulent the disease produced. This concept would explain the tendency of long established diseases to decrease in severity at the same time that they are becoming more prevalent.

This adaptation to a parasitic mode of existence is indicated in a variety of ways. The nutritive requirements of some of the pathogenic bacteria, for example, such as the necessity for fresh blood, ascitic fluid and the like in laboratory media, suggest an adaptation to an environment in which these or similar substances are available—the tissues of the host. The optimum temperatures for the pathogenic bacteria are, without exception, the body temperatures of their host, the human type of tubercle bacillus grows best at 37° C. but the avian type is presumably adapted to the higher body temperature of the bird, 41° to 42° C.

The question of whether a host may, through long association, become adapted to a parasitic bacterium to such a degree that the presence of the microorganism is either necessary or of advantage to the continued existence of the host is an open one. In certain cases the presence of a parasitic bacterium

⁵¹ Cf. Smith, Theobald *Parasitism and Disease*, Princeton University Press, Princeton, 1934.

There is, perhaps, something to be said for the term *aggressive action*, if we can so define it as to make it fill a gap in our terminology. It would seem to be most usefully employed as indicating an action on the cells or body fluids that is not directly cytotoxic, or of which the directly injurious effects are minimal, but which so interferes with the defence mechanism of the host as to favour, specifically or non-specifically, the multiplication of bacteria within the tissues.

bears a significant relation to the assimilation of food by the host; such, for example, is the case with respect to the leguminous plants and the root nodule bacteria, and the herbivorous animals and cellulose-decomposing microorganisms. Whether the abundant intestinal flora of man and other animals in general functions in a similar fashion has been the theme of considerable speculation and some investigation. Nuttall and Thierfelder early showed that guinea pigs removed by cesarean section and kept in a sterile environment survived for ten days or so, but Schottelius was not successful in rearing bacteriologically sterile chicks. Nutritional inadequacies of the chick diet apparently accounted for these results, for it was later shown that chicks could be raised for as long as forty days in a bacteria-free environment. The work of Reyniers⁵⁴ and his colleagues in recent years has shown that not only chickens, but a variety of higher animals such as guinea pigs, rabbits, rats, etc., may develop in the complete absence of bacteria. It appears likely, therefore, that an intestinal flora is not essential to the continued existence of some of the higher animals, but whether it may be an advantage is as yet uncertain.

of cases, a concentration over 1/100 to 1/20 unit per ml. of blood ensures a negative Schick reaction.

The proportion of persons with diphtheria antitoxin in the circulating blood varies in a striking and characteristic way as we pass from birth through childhood and adolescence to maturity and old age. Table 75 sets out the extensive figures recorded by Zingher (1923), where the percentage of positive reactors is tabulated.

At about 6 months of age just over half the infants react positively. The percentage of positive reactors then rises rapidly and between 8 months and 3 years fluctuates about an average of 88 per cent. After this, there is a continuous fall, at first rapid, then more gradual, till at the allotted span of three-score years and ten the proportion has dropped to approximately 5 per cent.

TABLE 75

COMPOSITE TABLE SHOWING PERCENTAGE OF SCHICK-POSITIVE REACTORS IN VARIOUS AGE GROUPS IN NEW YORK CITY AND NEW JERSEY.

The Origin of the Natural Antitoxins.

The most generally accepted view of the immunological events underlying this observed fluctuation in skin-sensitivity to diphtheria toxin is as follows. Most new-born infants have circulating antitoxin acquired passively from their mothers—mainly by passage to the foetus during pregnancy, in part perhaps with the colostrum in the early days of suckling. This passive congenital immunity, like all other types depending on the passive acquirement of antibodies, will be relatively short-lived. A careful study of the disappearance of antitoxin from the blood of an infant whose mother was highly immune is recorded by Neill and his colleagues (1932). From infancy onwards the child will be exposed to the risk of infection, increasing from year to year during the earlier part of school life. Some children

THE CLASSIFICATION OF BACTERIA

The classification of bacteria presents peculiar difficulties that stem more or less directly from their simplicity of structure. Since taxonomy in general rests on a morphological or anatomical basis, the relationship, phylogenetic or otherwise, of bacteria to the higher forms is difficult to define, and the interrelations of the bacteria themselves present problems to which taxonomy has, to date, offered no entirely satisfactory solution. A consequence of this structural simplicity is the widespread use of physiological characters in the differentiation of the bacteria into genera and species, characters whose counterparts among the higher organisms are, in general, regarded as of but minor taxonomic importance. As has been pointed out previously, differences that are quite possibly trivial biologically are often of great practical importance and hence have come to assume a taxonomic significance that may often be entirely undeserved. In other cases the biological importance of a given characteristic or group of characteristics is unknown, and the inability to assess the significance of characters proposed as differentials has led to disagreement among bacteriologists.

Such a situation clearly does not lend itself to order and system nor, and perhaps most important of all, does it allow the development of a classification which is based upon characters of fundamental significance and which shows the biological or genetic relationship of these organisms to one another. The practical consequences are two—there is no classification of bacteria which is generally accepted in more than its primary subdivisions, and, second, the bases upon which various groups of bacteria are classified differ widely, as will appear, from one group of organisms to another. It should be emphasized, therefore, that bacterial "species" are by no means analogous to the species of the zoologist or botanist and cannot be compared directly to them.

The phenomenon of bacterial variation, discussed in the previous chapter, is clearly of no small importance in the classification of these organisms. From the general biological point of view there is but little solid ground upon which a sound taxonomic structure can be built. In the practical identification of bacteria, however, such variations are not a source of great embarrassment. As has been pointed out, the majority of bacterial variations arise as a consequence of alterations in the environment and, in a working sense, may be regarded as adaptations. The observed uniformity of the morphology and biochemical properties of the bacterial culture is due to the fact that observations of these characters are always made in the same way. It is only when the procedure is varied, either in terms of the past history of the bacterial culture or in the

antibodies in the maternal blood must pass in order to reach the foetal circulation ; or that the route was necessarily *via* the placental vessels. Hartley's (1948) experiments with pregnant guinea-pigs passively immunized by diphtheria antitoxins prepared in different animals and refined by different methods indicate that uterine transmission is selective, homologous guinea-pig antitoxin passes to the foetus far more readily than the heterologous horse antitoxin, and salt-precipitated antibody globulins pass more readily than those altered and refined by peptic digestion (see Chapter 7).

Brambell and his colleagues (1948, 1949, 1950, 1951, 1952, 1953) record a similar selectivity in the pregnant rabbit, where the passage of horse and bovine agglutinin and antitoxin is much less than that of the corresponding antibodies prepared in the rabbit. In this animal they also found little evidence of placental transmission. After the establishment of the allanto-chorionic placenta, in the 15-day embryo, maternal antibodies reached the foetus *via* the uterine cavity, passing through the endoderm of the yolk sac splanchnopleure into the vitelline circulation, whose integrity was proved to be essential by the interruption of transmission when the vitelline vessels were ligated. In man, however the allanto-chorionic placenta appears to be the probable route of uterine transmission. They regard the vitelline route in the rabbit as analogous to adsorption of colostral antibody from the gut of new-born animals, since the yolk sac is morphologically an extension of the gut. They also record that antibody in the amniotic fluid, though it accumulates in the foetal stomach, does not reach the foetal circulation by this route.

TABLE 76

THE RELATIVE IMPORTANCE OF THE UTERINE AND MAMMARY ROUTES IN THE PASSIVE TRANSMISSION OF ANTIBODIES FROM MOTHER TO OFFSPRING. (After Mason, Dalling and Gordon.)

Species	Layers of Tissue between Maternal and Foetal Circulation	Importance of Uterine Transmission	Importance of Transmission by Colostrum.
Pig	5	—	+++
Ruminants	4	—	+++
Carnivores	2	±	+
Rodents, apes, man .	1	+++	±

In man, antibody is present in the colostrum, though usually in small amounts, unless the blood antibody levels are high. Immediately after delivery, for example, the diphtheria antitoxin content of the colostrum may be as high as one-third that in the blood, but it drops steeply during the first days of lactation. Some transmission *via* the colostrum appears to take place (Sugg 1935, Magara 1936); though Schubert and Grunberg (1949), who recorded in human colostrum significantly higher typhoid agglutinins than in the blood, found that none of this antibody was absorbed by the babies at breast. In sheep immunized with diphtheria toxoid, mean concentrations in the colostrum at parturition as high as 7.8 times those in the serum are recorded, the concentration, however, drops rapidly within a day to that in the serum, as a result of suckling the lambs (Barr *et al.* 1953). Mice differ from other rodents in the table in that the mammary route appears in some cases to be more important than the placental. Thus, a higher degree of milk transmission of antibodies was demonstrated experimentally in mice infected with herpes virus (Berry and Slavin 1943) and with *Trypanosoma duttoni* (Culbertson 1940); and, in mice infected with Coxsackie virus, the passive transfer of maternal antibody appears to be solely colostral (Melnick *et al.* 1950). In mares with high-titre tetanus antitoxin, Lemétayer and his colleagues (1947) found some uterine transmission, though mammary transmission predominated.

way in which the test is conducted, that variability becomes apparent and the illusory nature of the supposed constancy of these organisms is demonstrated.

The question of whether bacteria should be regarded as members of the plant or animal kingdoms is no longer considered of great importance. Possessing characteristics of both, these organisms may be regarded as a connecting link between the plants and animals. Using the term bacteria in its broad sense, the microorganisms included under this head make up a continuous series of types which appear to connect the two kingdoms. The so-called higher bacteria, the sheathed, filamentous forms, are closely akin to the fungi, bacteria such as the tubercle bacillus and the diphtheria bacillus appear to be further removed from the plants but show some fungoid characters, such as tendencies to branching and filament formation. Among the well-known forms such as the streptococci, staphylococci, sporulating rods and gram-negative intestinal forms, the morphological relations to the fungi are less apparent, organs of locomotion appear, and with the spiral forms the bacteria merge into the protozoa. Physiological characters and the evidence of chemical composition of the cells tend to reinforce this intermediate position. The metabolism of these organisms is chemosynthetic, an animal-like character, but the ability to utilize ammonium salts as a source of nitrogen suggests a plant type of physiology, nucleic acids found only in plant cells or only in animal cells have all been found in the bacteria. It was proposed many years ago that a third kingdom be created for these organisms, the *Protista*, but since the dividing lines between such a third group and the plants on the one hand and the animals on the other are as vague as that between the plants and animals, the proposed new kingdom would solve no difficulties and has never been accepted. It is generally agreed, however, that the sum total of bacterial characters allies them more closely to the plants than to the animals, and they are classified with the plants as *Schizomycetes* or fission fungi (German *Spaltpilzen*). The relationship of the *Schizomycetes* to other plants may be indicated as follows:

- Phylum I. *Thallophyta*, plants without distinction of root, stem and branch
 - Subphylum 1—the algae
 - Subphylum 2—the fungi—thallophytes lacking chlorophyll
 - Class I. *Schizomycetes*—the bacteria
 - Class II. *Myxomycetes*—the slime molds
 - Class III. *Phycomycetes*—the algae-like fungi
 - Class IV. *Ascomycetes*—the fungi forming ascospores
 - Class V. *Basidiomycetes*—the fungi forming basidiospores
- Phylum II. *Bryophyta*—the mosses
- Phylum III. *Pteridophyta*—the ferns
- Phylum IV. *Spermatophyta*—the seed-bearing plants

Although the interrelationships of the organisms included under *Schizomycetes* present problems which are, in many essentials, new to the taxonomist, certain "natural" groups are apparent. Of these the most obvious is that based on morphology, with primary division into spherical, rod-shaped, spiral and filamentous forms, and subdivision on the basis of spore formation, presence and location of flagella, and staining reactions to the gram and acid-fast stains. The earlier classifications, the better known of which are those of Migula and of Lehmann and Neumann, were made on this basis. These classifications

age is entirely due to natural active immunization resulting from the reception from without of specific stimuli in the shape of clinical or subclinical infections? This hypothesis has certainly not been placed beyond dispute. It has indeed been vigorously disputed, particularly by Hirszfeld (1926) and his colleagues.

Hirszfeld believes that all the normal antibodies should be regarded as "biochemical organs," with which the individual is endowed as the result of his evolutionary history. These "biochemical organs" ripen, or come to maturity, at different periods in his own individual development; just as the various organs and tissues of the body come to full maturity at different ages. As we speak of a "morphogenesis" through which each individual passes, so we should think of a "serogenesis" which forms an integral part of normal development. The time at which any particular antibody normally makes its appearance may be regarded as the period of "immunological crisis" for that particular antibody, and marks the establishment of a "biochemical reflex" on which the production of that antibody depends. Until the biochemical reflex has become established attempts at immunization with the particular antigen concerned will have little effect. Hirszfeld does not deny that specific, or non-specific, stimuli from without may play some part in accelerating the production of particular antibodies, or in increasing their concentration; but he would relegate such influences to a very secondary place. He would not regard the presence in the blood stream of antibodies acting on a particular bacterium as valid evidence of past or present infection with the bacterium in question. Above all, he would not accept the view that the antibody-forming apparatus is a *tabula rasa*, on which environmental stimuli can write at will. It is a complex mechanism with its possible activities fixed and ordered by the phylogeny of each animal species; and it will therefore respond to the appropriate stimuli and to no others.

It will be simpler to discuss the more general aspects of Hirszfeld's views when we have dealt with the origin of antibacterial sensitizers, and to confine our immediate attention to antitoxic immunity, noting in passing that the problem is in no sense a purely academic one but has important bearings on many problems of diagnosis and prevention.

Perhaps the most significant data, supporting Hirszfeld's contention, are to be found in observations (Hirszfeld, Hirszfeld and Brokman 1924, Hirszfeld and Hirszfeld 1927) which suggest a linkage between the inheritance of the power to produce antitoxin and the power to produce the iso-agglutinins which determine the human blood-groups (see p. 1236). From these records Hirszfeld draws the following conclusions. When both parents are Schick-negative the children will be Schick-negative, except during the first few years of life. When both parents are Schick-positive the children will be Schick-positive, and will remain so throughout life. When one parent is Schick-negative and the other Schick-positive the children who belong to the same blood-group as the Schick-negative parent tend to be Schick-negative, those who belong to the same blood-group as the Schick-positive parent tend to be Schick-positive (see also Tamaki *et al.* 1936). The validity of these observations has, however, been questioned by Rosling (1928), who examined 50 children over one year of age whose parents belonged to different blood-groups and reacted differently to the Schick test. He found that 23 children gave the same Schick reaction as the parent to whose blood-group they belonged, while 27 reacted differently.

A negative is notoriously difficult to prove; and we cannot assert that no child has ever developed diphtheria antitoxin except in response to the specific stimulus provided by diphtheria toxin. We can, however, study the frequency of negative and positive Schick reactors in different samples of the population, and correlate our findings with the history of exposure to infection, so far as such a history is obtainable. If we find that free or frequent exposure to infection is consistently associated with a high percentage of negative reactors, and that population groups relatively free from any risk of infection show a notably low percentage of negative

exerted a strong influence on bacterial taxonomy and resulted in the naming of a great many species of bacteria, many of which persist in current classifications.

Morphology is, however, not a sufficient basis for the separation of bacterial species, for many morphologically similar organisms may be quite different in other respects. Physiological differences, generally readily determinable in the laboratory, have been widely used. In fact, one of the early classifications, that of Orla-Jensen, depended upon nutritional differences for the primary subdivision into three main groups:

1. The autotrophic bacteria which, like the green plants, require neither organic carbon nor organic nitrogen compounds
2. Bacteria which require organic carbon compounds but can dispense with organic nitrogen, using ammonium salts or other inorganic compounds of nitrogen
3. Bacteria which, like the higher animals, require both organic carbon and organic nitrogen compounds

A number of workers, especially Kluyver and van Niel,¹ are of the opinion that comparative physiology should constitute the primary basis of separation, rather than being subordinate to morphology.

Beyond such primary subdivisions, classification becomes increasingly difficult and it is quite clear that this is so because not nearly enough is known of the phylogenetic relationships of the bacteria to one another for a detailed classification with definition of genera and species. This question has been discussed in some detail by van Niel² who shows that as yet any classification can be little more than a key and species only "form" species, that is to say, no more than convenient handles.

Bacterial classification has evolved through some sixty odd schemes to perhaps half a dozen current today.³ The criteria made use of are, in the order of approximate fineness of distinction made:

- (1) morphology—both gross and microscopic,
- (2) physiology—biochemical properties,
- (3) pathogenicity—of the disease producing bacteria,
- (4) immunology—the antigenic structure of the bacterial cell.

Of the current classifications that of the Bergey Manual⁴ is by far the most detailed and is the only one that need be considered here. It developed from the earlier classification of Chester and the work of a committee of the Society of American Bacteriologists, but is not, as is sometimes supposed, the official expression of the views of the Society. The Bergey classification has gained ascendancy in this country in recent years, though it is seldom used outside the United States.

An abridged outline of the Bergey (1948) classification is given in the accompanying diagrammatic form. It differs from the Bergey system in that the genus *Staphylococcus* is retained, and the tribe Hemophilae is not broken

¹ Kluyver and van Niel: *Centralbl. f. Bakt., Abt. II*, 1936, 94-369.

² van Niel: *Symp. Quant. Biol.*, 1946, 11-285.

12 years of age. Antitoxin was demonstrated in some of the negative reactors. Yet diphtheria is said to be unknown among the Eskimos.

Kleine and Kroó (1930) tested 101 East African natives by the Schick reaction; 95 of these were children between the ages of 6 and 15, the remaining 6 were adults. In no case was a positive reaction obtained. The toxin employed was subsequently retested and found to have lost none of its activity. Specimens of serum were obtained from 11 of the natives and tested for antitoxin; 10 of these contained antitoxin in considerable amount (0.05 A.U. to more than 1 A.U. per ml.). It is clear therefore that the East African native frequently forms diphtheria antitoxin early in life; yet, according to Kleine and Kroó, this population is not, so far as is known, exposed to infection with diphtheria. (See also Parr and Avery 1926-27, Parr, Goodale and Kirschner 1930.)

Grasset and his colleagues (1933) record a high frequency of natural diphtheria immunity among the Bantu of South Africa, as judged both by Schick tests and antitoxin titrations. They note, however, the occurrence of diphtheria among the populations concerned, and adopt without question the view that the antitoxin has been produced in response to infection. Murray (1943) provides more definite evidence. Among the Johannesburg Bantu clinical diphtheria was rare, but, as Grasset found in his series, the Schick-positive rate was low. In rural school children it was 8.0 per cent. and in urban children 13.7 per cent. The corresponding carrier rates of virulent diphtheria bacilli were 1.8 per cent. in the urban, and 3.2 per cent. in the rural; and though the Schick-positive and the carrier rates did not vary together, immunization was associated with the presence of carriers among the children. It is noteworthy that there was little clinical diphtheria among these Bantu children, as compared with white children in the same district, among whom a similar carrier rate was associated only with an epidemic of diphtheria; no bacilli were found in their throats in non-epidemic periods. Murray (1942) concludes that environmental conditions were in part responsible for the high level of antitoxic immunity of the Bantu, and that the absence of clinical diphtheria in spite of the relatively high carrier rate was due to an ability, perhaps racially determined, to produce antitoxin quickly in response to the specific antigenic stimulus.

In only a few other instances do such surveys include a record of the carrier rate of diphtheria bacilli, or of hæmolytic streptococci, among the population concerned. Wells (1933), records a study of the Schick reactions of central and polar Eskimos, in which a proportion of tests were confirmed by antitoxin titrations, and throat swabs were obtained from all persons examined. He reports the frequent presence of bacilli morphologically resembling *C. diphtheriæ*, and states that four strains gave the typical fermentation reactions, and one strain showed some degree of virulence. These findings clearly tend to throw doubt on the significance of the observations recorded by Heinbecker and Irvine-Jones (1928), but it can hardly be said that the presence of toxigenic diphtheria bacilli was established with certainty.

A study by Asbelew and Margo (1932) of the Schick and Dick reactions of 103 of the 250 inhabitants of the Arctic island of Kolgijew is very difficult to reconcile with the *Durchseuchung* hypothesis—the view that antitoxin is produced only or mainly as the result of infection. With the exception of one girl of 8 years all persons examined were Schick-negative, and with the exception of one doubtful case all were Dick-negative. The antitoxin content of the blood was unfortunately not determined. Diphtheria and scarlet fever had never been reported on the island. Swabs were obtained from the throats of 168 persons, and from the noses of 93. No diphtheria bacilli were isolated, and hæmolytic streptococci were found in only four swabs.

There is great need of further studies in which full bacteriological and immunological tests are carried out on isolated or semi-isolated populations.

Although they are not complete, in this particular sense, the observations of Dungal (1932) on diphtheria in Reykjavik are particularly instructive. From 1926 onwards diphtheria has been very rare, not only in Reykjavik but in Iceland as a whole; but in the preceding years there was a moderate prevalence, reaching its peak in Reykjavik in 1921 with an attack

experimental evidence is, of necessity, scanty ; but so far as it goes it is demonstrative.

Guthrie, Marshall and Moss (1921) collected 8 volunteers and determined their reaction to the Schick test ; 4 reacted positively and 4 negatively (including 2 pseudo-reactions). The throat of each of these 8 volunteers was swabbed with a virulent culture of the diphtheria bacillus. The four positive reactors developed clinical diphtheria ; the 4 negative reactors, possessing natural antitoxin at or above the Schick-immune level, developed no illness, though 3 of them became carriers.

The main body of evidence on which we rely in concluding that natural antitoxin confers natural immunity has, however, been collected during the course of extensive clinical and epidemiological studies on diphtheria and scarlet fever (see Chapters 61 and 66). There is no doubt that a person whose blood contains antitoxin at or above the Schick-immunity level is far less likely to contract diphtheria than a Schick-positive person. If he does so, the attack will often be mild and will seldom prove fatal. The nature of the evidence that associates natural antitoxic immunity with effective resistance to scarlatinal infection is of the same general kind as in the case of diphtheria.

The Natural Antibacterial Antibodies

It has long been known that there are naturally occurring agglutinins, bactericidins and other sensitizing antibodies, just as there are naturally occurring antitoxins ; but the ground that has been surveyed in the two cases is rather different. We have seen that our knowledge of the distribution and mode of origin of the natural antitoxins is, in the main, derived from the study of diphtheria and scarlet fever in man. Our knowledge of the distribution and mode of origin of the antibacterial sensitizers is, in the main, derived from studies on their occurrence in different species of animals.

One of the earliest studies made was by Burgi (1907), who tested sera from the dog, guinea-pig, rabbit, goose, hen, sheep, goat, horse, ox and man against suspensions of various bacteria, including *V. cholerae*, *Salm. typhi*, *Bact. coli*, *Past. arisepitica*, *Staph. aureus* and *Proteus vulgaris*, and noted well-marked agglutination in many instances, often to a relatively high titre. However, the various sera tended to have much the same order of activity, against whichever species of organism they were tested ; and this order was in general maintained when the sera were tested for their ability to flocculate suspensions of mastic.

Gibson (1930) carried out similar experiments with sera from the ox, rabbit, guinea-pig, horse, sheep, pig, rat, cat and man, tested against *Proteus* X19, *Ps. pyocyanea*, *Salm. typhi*, *Salm. paratyphi A*, *Salm. paratyphi B*, *Salm. enteritidis*, *Sh. flexneri*, *Sh. dysenteriae*, *Proteus morgani*, *Bact. friedlander*, several strains of *Bact. coli* and *V. cholerae*. He found, like Burgi, that the sera tested tended to fall in a definite order with regard to their power of agglutinating a wide variety of bacteria. Ox sera were the most active ; pig and horse sera were somewhat less active ; sheep serum was next in order ; while human, cat, rabbit and guinea-pig sera, in that succession, showed progressively weaker effects. Rat serum was the weakest of all. Similarly the different bacterial species showed a definite order of sensitivity to agglutination. *Sh. flexneri*, *Bact. friedlander* and *Ps. pyocyanea* were the most sensitive, and certain strains of *Bact. coli* the least sensitive. By absorption experiments, this agglutination proved to be dependent on specific antibodies ; but since any one organism, in addition to removing completely the specific agglutinin acting on itself, might reduce the titre of the serum for other organisms, and a similar general reduction in titre might be produced by adsorption with some non-specific agent such as charcoal, he concluded that another non-specific serum constituent was concerned in the

Leptospira	spirochetes of infectious jaundice and Weil fever (p. 746)

only to a few. The specificity of the flagellar agglutinins in normal sera seems to have been clearly established, and the evidence is definitely in favour of the specificity of some, at least, of the agglutinins acting on the antigens at the surface of the bacterial cells. These agglutinins, flagellar and somatic, are, it should be noted, usually present in low titre only ($1/5$ – $1/40$ or thereabouts). The evidence with regard to the specificity of the bactericidal antibodies is more conflicting; but results indicating specificity have been recorded, and if somatic agglutinins are present we should expect them to exert a bactericidal action in the presence of complement. (For examples of natural antiviral antibodies, see Chapter 87.)

The conclusion that the natural antibacterial sensitizers are specific does not, of course, imply any particular hypothesis as to their mode of origin; it assumes only that they unite with certain bacteria because of a physico-chemical correspondence of certain specific combining groups. Moreover, even though an antibody results from an external antigenic stimulus, it may have been formed in response to antigens of an entirely different origin from those in the bacterial suspension used to detect it.

We need not, however, assume that all specific natural antibodies are induced by active immunization. A "natural" antibody and an "immune" antibody, both acting on the same bacterium, must each possess chemical groupings with a specific affinity for groupings borne by the bacterium; but, if the natural antibody has arisen in some way other than in response to infection with the actual bacterium concerned, it is quite possible that the chemical correspondence between its active groupings and those on the bacterial surface will be less close than in the case of an antibody produced in response to infection or artificial immunization. Certain experimental findings are consistent with such a possibility. It is, for instance, a very general experience that some, at least, of the "natural" antibodies require, for their removal from a serum, an absorbing dose of bacteria very much larger than that required for the removal of the same amount of an "immune" antibody.

If we adopted this view we should expect that the antibacterial antibodies demonstrable in any random sample of a human or animal population would be of two kinds, those arising as the result (*a*) of contact, whether infective or not, of the tissues with the bacterium on which they act, or with other, though related, antigenic material, and (*b*) those arising in some other way. This brings us directly to the question of their origin under natural conditions.

Some Examples of Natural Agglutinins.

It is, of course, well established that certain kinds of "natural antibodies" are produced in the absence of any environmental stimulus, and in accordance with definite genetic laws.

The best example is provided by the isohæmagglutinins that divide mankind into different blood-groups.

Landsteiner (1901) distinguished the principal blood-groups into which the human race may be divided, and showed that this grouping depends, in the main, on the distribution of two different antigenic constituents, which may be present together, or separately, or may both be absent. There are two corresponding antibodies, and these are so distributed that neither antibody is present in the blood of an individual whose red cells contain the corresponding antigen. By determining the antigens present in any sample of blood it is therefore possible to assign it to its correct group. The antigens are referred to by a capital letter, the antibodies by Greek letters, and the blood-group

down into genera other than *Hemophilus*. These and minor variations which appear later have been retained to keep the nomenclature from differing too widely from practice in other than current American literature. For example, the name *Vibrio comma* for the cholera vibrio is not used outside the Bergey classification; over 98 per cent of the papers published on this bacterium in the past 20 years are not American, and consistently use the name *Vibrio cholerae*. Abridged keys for the differentiation of the better known species of bacteria are included in subsequent chapters.

Nomenclature.⁵ Throughout the development of bacteriology names have been given these organisms in a haphazard fashion and often with singular disregard for the conventions of botanical nomenclature. In general, however, a bacterium has a generic name, always written with a capital letter, which may or may not be descriptive (for example, *Bacillus*—a small rod; or *Pasteurella*—in honor of Pasteur) and a specific name which may be an adjective (*albus*—white) or a noun indicating possession (*Clostridium welchii*—Welch's clostridium) or a noun in apposition (*Bacillus radicolola*—the root-dweller bacillus). The practice of indicating the author of the name, as in *Bacillus subtilis* Cohn, is not as common in bacteriology as in zoology or botany. The use of trinomial and quadrinomial names such as *Granulobacillus saccharobutyricus mobilis nonliquefaciens* is obviously highly undesirable. Trinomials are occasionally useful in the designation of varieties of subspecies. Common names are, of course, used; terms such as Friedländer's bacillus, the typhoid bacillus, etc., are frequently encountered.

Genera. Perhaps one of the greatest difficulties the bacterial taxonomist labors under is the paucity of genera. The question of what degree of difference shall be judged sufficient to establish new genera is one to which there is as yet no satisfactory answer. At the present time considerable confusion and lack of uniformity still exist. In a number of instances new generic names have obtained wide currency among bacteriologists in many parts of the world, partly, doubtless, because they are applied to fairly distinct groups of microorganisms and have genuine classificatory value. Such are *Brucella* (for the bacilli of undulant fever of man and contagious abortion of cattle), *Salmonella* (for the paratyphoid bacilli) and *Pasteurella* (the bacilli of hemorrhagic septicemia in domestic animals and the bacilli of plague and tularemia); the name *Shigella* for the dysentery bacilli has gained a considerable degree of recognition. Without any formal international agreement, these names can be said to have won international standing.

In a number of instances it seems necessary to mention both old and new names whenever a microorganism is referred to. Few bacteriologists venture to use the name *Serratia marcescens* without explaining that they mean *Bacterium prodigiosum* or *Bacillus prodigiosus*, or *Gaffkya tetragenus* without the equivalent *Micrococcus tetragenus*. Similarly the adherence of bacteriologists to various taxonomic schemes gives rise to a series of names for a microorganism, the familiar typhoid bacillus may be *Bacterium typhosum*, *Bacillus typhosus*, *Salmonella typhi*, *Eberthella typhosa* or *Salmonella typhosa*.

For the present the bacteriologist seems to have no escape from using a

⁵ Rules of nomenclature, proposed but not officially adopted, are discussed by Buchanan, St. John-Brooks and Breed Jour. Bact., 1948, 55:287.

British and white American people, about 85 per cent. of the population are Rh-positive, the remainder Rh-negative. The Rh-positive persons, are in fact those who, among the 8 sub-types of the Rh system, possess the D antigen. When an Rh-negative woman mates with an Rh-positive man, the foetal erythrocytes may be Rh-positive, and in a certain number of cases, depending perhaps on the condition of the placenta, the Rh antigens of the foetus are transferred to the mother, and induce the formation of Rh-agglutinins. Towards the end of pregnancy, these agglutinins appear in the circulation of the foetus, and, uniting with the foetal erythrocytes, sensitize them to lysis, in a manner analogous to the sensitization, let us say, of Group A cells transfused into a Group B person with natural α agglutinins in his serum. The resulting destruction of the red cells may lead to the death of the foetus and abortion, or the birth of an infant with the syndrome known as erythroblastosis foetalis (Levine, Burnham, Katzin and Vogel 1941). Certain other of the Rh antigens, but not all of them, are capable of inducing hæmolytic disease. We have in this disease a clear-cut example of uterine transference of foetal antigen to the mother, and then of maternal antibody to the foetus. The Rh antibody may also be transmitted by the colostrum. There is clearly a difference between the action of maternal Rh-agglutinins and the maternal α and β agglutinins, for it is only rarely that serious blood destruction occurs in infants of the A, B, or AB groups whose mother's blood contains agglutinins for A, B or AB cells. We may postulate a selective transmission of Rh, but not α or β agglutinins; or that the infants are insusceptible to α and β agglutinins (see, e.g., Tovey 1945); or the agglutinins are more quickly eliminated from the infant's circulation (Wiener 1951a). It has been suggested that the cells of the infant are protected from α and β agglutinins of the mother by water-soluble Group A or B substances which are present in the tissues and body fluids of the infant, and which unite with any maternal agglutinins that reach the foetus. Group A and B cells are characterized by viscous mucopolysaccharides (see the next section), which occur in a water-soluble form in the tissues and body fluids of most persons of the corresponding blood-group—e.g., in the saliva, gastric juice and in the secretion of pseudomucinous ovarian cysts. Their presence in the body is determined genetically by an independent "secretor" gene, S. The Rh substance, on the other hand, is confined largely to the erythrocytes (Levine and Katzin 1941, Wiener and Forer 1941) and, being absent from the tissue fluids, is not available for the neutralization of maternal Rh-agglutinins. (For a full discussion, see Levine 1943.) The validity of this explanation is not yet established.

Apart from the direct hazard of transfusion with cells for which the recipient's serum may contain natural isohæmagglutinin, there is the less direct but equally real hazard of transfusion reactions in persons whose serum, as a result of previous transfusion, or, in women, of pregnancy with a foetus of a different blood-group, contains hæmolysins for the donor's cells. As with hæmolytic disease, these reactions are commonly due to Rh agglutinins, and to antibodies for antigens of the systems known as Kell, Duffy and Kidd; though on rare occasions other antigens are responsible.

The hæmagglutinins so induced usually differ from iso-agglutinins in reaching higher titres, which tend to decline when the stimulus ceases; in reacting with R.B.C. better at 37° C. than at room temperature; and in a greater heat resistance. Moreover, though they may be detectable by the orthodox agglutination technique in 0.85 per cent. saline, they are commonly present as inapparent agglutinins, requiring special techniques for their demonstration (see Chapter 7). They also appear to pass readily from mother to foetus, and are important in hæmolytic disease. The titre of α - and β -iso-agglutinins, on the other hand, is low and tends to be constant. The antibodies are most active at room temperature, and are relatively heat-labile; they are not important in hæmolytic disease. The distinction is not always clear cut, but it is sufficiently striking to lend colour to the view that the "natural" hæmagglutinins are produced differently from "immune" hæmagglutinins; and are the result of "serogenesis". On the other hand, their appearance after birth, and the widespread occurrence in nature—in the saliva of secretors, in other mammals and mammalian foodstuffs, in plants and microbes (see next section)—of antigens

double set of generic names for certain organisms, or from using the older, albeit nomenclatorially unjustifiable, names for others, while welcoming certain new and useful generic designations such as *Brucella* and *Salmonella*. Uniformity, consistency and strict adherence to the rules of biological nomenclatorial practice are perhaps in the future.

Species. The differentiation of species is made for the most part on a physiological basis. A single character is hardly sufficient, particularly in view of the facility with which variation occurs. The use of a number of such characters is the rule, but difficulties are frequently encountered when intermediate forms occur. For example, *Bact. coli* and *Bact. aerogenes* are almost universally regarded as different species and in the Bergey classification are put into different genera, *Escherichia* and *Aerobacter* respectively. Yet forms intermediate between the two are so commonly encountered that it sometimes seems a doubtful procedure to attempt to separate these so-called coliform bacteria.

Types. Immunological differentiation is generally regarded as not of species status though it may sometimes coincide with species differentiation on a physiological basis. Conversely, minor cross reactions between species are not indicative of species identity. There are some exceptions to the former, however, and many workers divide the genus *Salmonella* into species on the basis of antigenic structure. Immunological differences are of very considerable value, particularly for epidemiological purposes, and are usually the basis of distinction of types within a species. Thus the streptococci are divided into groups, designated A, B, C, etc., on the basis of one kind of antigen, and into arabic numbered types within and across species by another. The pneumococci are similarly divided into numbered types on the basis of capsular antigen. *Clostridium botulinum* is separated into types, A, B, C, etc., on the basis of the immunological specificity of the toxin, and these have no relation to the immunological character of the cell substance. There is, then, no general practice with respect to type differentiation. Physiological differences within species are usually not used to differentiate types, and the biochemical reaction is simply given as variable.

stimulate the production of heterophile antibody; and in general it appears that those species that contain heterophile antigen in their red corpuscles do not contain it in their tissues, at least in the full and effective antigenic form.

It soon became clear, from absorption experiments of the usual type, that the hæmolysin produced by the rabbit in response to guinea-pig's kidney was not identical with that produced in response to sheep's corpuscles, which is a mixture of hæmolysins, only one of which corresponds to the heterophile antigen. (See, e.g., Tomcsik and Fisher 1946, Tomcsik and Schwarzweiss 1948.)

Only animals of the rabbit type—those not containing heterophile antigen in their tissues—are capable of producing heterophile antibody in response to guinea-pig's kidney or other suitable tissue. It is also of particular interest that certain normal antibodies are of the heterophile type—for instance, the natural hæmolysin for sheep's red cells that is found in the serum of rabbit and man (Friedemann 1917). In human serum, this reaction may depend on the α -iso-agglutinin, for, as Schiff and Adelsberger (1924a b) showed, there is a close antigenic relation between the heterophile antigen and the Group A substance.

The constitution of the heterophile antigen appears to vary with the organ in which it is found. According to earlier workers (Iwai 1917, Georgi 1919, Taniguchi 1921) the specific component (hapten) is associated with lipid constituents of the tissues, especially the alcohol-soluble "lecithin" fraction. The heterophile antibody, in addition to acting as a hæmolysin for sheep cells, forms a precipitate and fixes complement when mixed with an emulsion of these lecithin fractions of tissues containing heterophile antigen. The lipid extracts are not antigenic, but can be made so by mixing with a suitable protein, the resulting antisera containing both heterophile antibodies and antibodies specific for the protein used (Landsteiner and Simms 1923). These haptens were apparently lipopolysaccharide in nature (Landsteiner and Levine 1925, 1927; but see also Renaux and Thomas 1942).

The Group A substance, which in pure form is non-antigenic in the rabbit (i.e., a hapten), has proved to be a viscous substance made up of polysaccharide units, partly hexose, partly N-acetylglucosamine, and a number of amino-acids (Goebel 1938, Landsteiner and Harte 1940, 1941, Morgan and King 1943, King and Morgan 1944, Aminoff, *et al.* 1950).

This substance, or the mucopolysaccharides closely resembling it, is found in mammals other than man—for example, in the gastric mucosa of swine, cow and horse. Substances either identical with or very like the B substance, and the H substance found in Group O cells, are also present in the secretions of other mammals; they have been extensively studied by Morgan and by Kabat, whose reviews should be consulted by those desiring detailed information (Kabat 1949, 1952, Morgan 1953). A remoter instance of an antigenic relationship of the A, B and O substances is provided by Type XIV pneumococcus; horse antisera prepared against this organism agglutinate the cells of all four major blood-groups. All three substances contain L-fucose, D-galactose and N-acetyl-D-glucosamine; and the Type XIV pneumococcal polysaccharide contains D-galactose and D-glucosamine. Cross-reactivity of the blood-group substances with this antiserum is greatly increased by a degree of hydrolysis which destroys blood-group specificity—a procedure which removes the L-fucose residues (see Kabat 1952).

✓ As we have indicated in Chapter 8, a number of bacteria contain the Forssman antigen or substances immunologically related to it. In *Sh. dysenteriae*, the Forssman hapten is associated with the lipopolysaccharide moiety of the somatic antigen (Meyer and Morgan 1935, Meyer 1938, Morgan and Partridge 1940, Davies and Morgan 1953, Davies *et al.* 1954). As Morgan showed, the hapten from *Sh. dysenteriae* is not antigenic, but can be made so by reunion with the protein moiety of the antigen (see p. 303). The Group A substance can in the same way be made powerfully antigenic by union with this *Sh. dysenteriae* protein; and the resulting antigen, like the complete antigen of *Sh. dysenteriae*, stimulates the production of heterophile antibodies. This interesting demonstration, together with that of Landsteiner and Simms (1923), suggests a means whereby heterophile

THE RELATION OF BACTERIA TO DISEASE

Prior to the discovery of the causal relation of bacteria to the infectious diseases, these afflictions were regarded as an outward manifestation of the activity of some metaphysical or supernatural agency. A common belief, and one that still persists among some primitive peoples, was that of demoniacal possession, the invasion of the human body by the demon, taking the form of punishment for misdeeds or a consequence of individual failure to take adequate precautions against malignant spirits. When the advance of knowledge brought a larger measure of understanding of the structure and functions of the human body, a new and semiscientific theory of disease sprang into being and, although not entirely displacing the concept of demoniacal invasion, attained world-wide influence. The Hippocratic theory of disease, as it was called after its founder, the Greek physician Hippocrates, postulated four bodily humors, blood, phlegm, yellow bile and black bile. Health consisted of a proper mixture of these humors, disease an improper mixture. Although supplanted to a mild degree in the seventeenth century by more complex and mystical theories such as the homeopathy of Hahnemann, the Hippocratic doctrine of humors was dominant throughout the middle ages and even yet colors much medical thought and practice.

Amid the vagueness and confusion of these half mystical hypotheses emerged the tangible and definite germ theory of disease. As already pointed out, the germ theory of disease is the legitimate offspring of the germ theory of fermentation, and owes its origin to the memorable investigations of Louis Pasteur. The belief that the infectious diseases are caused not by demons or improper mixtures of humors or by any spiritual dynamic derangement but by microscopic plants and animals is now securely established on a firm experimental foundation.

✓**Koch's Postulates.** The unequivocal proof of a suspected causal relation between a given bacterium and a particular disease is dependent upon the development of a logical chain of experimental evidence which is often formalized as a series of postulates. These are commonly known as Koch's postulates although there is no evidence that Koch himself expressed these experimental steps in terms of formal "postulates." There are four of these:

- (1) The bacterium must be observed in every case of the disease.
- (2) The bacterium must be isolated and grown in pure culture.
- (3) The bacterium, in pure culture, must, when inoculated into a susceptible animal, give rise to the disease.
- (4) The bacterium must be observed in and recovered from the experimentally diseased animal.

specificity that proves to be based on an accidental correspondence of the surface groups of a mammalian serum protein with those of a substance characterizing a bacterial species—a correspondence apparently not induced by the stimulus of a related antigen. It illuminates the problem of the origin of natural antibody inasmuch as it indicates the possibility of an "antibody" formation that is independent of stimulation by the kind of antigens we discussed in Chapter 7. It may also be independent of the mechanism of antibody formation discussed in Chapter 50. However, in the rabbit immunized with human serum proteins Wood (1953) demonstrated the early production of Cx-reactive protein, and an association between its titre and that of the specific antibodies subsequently produced. Certain insoluble adjuvants to antibody formation (see Chapter 50) also induced its appearance. The Cx-reactive protein presumably comes from tissues newly formed or newly responding to an external stimulus; whether it comes from cells that later will produce specific antibody remains to be determined.

Heterophile antigens and antibodies other than those of the Forssman type occur in animal tissues. Thus Deicher (1926) records that the injection of horse serum into man induces the formation of agglutinins not only for sheep erythrocytes, but also for those of the rabbit, which contain no Forssman antigen. The distinction of these agglutinins from Forssman antibody was confirmed by Schiff (1937) who demonstrated them in man following injection of rabbit serum, which also contains no Forssman antigen. There appeared to be two antigens concerned, one specific for rabbit erythrocytes, the other shared with those of the sheep, horse and ox. Graña (1944) records similar antibodies in patients with hydatid cysts who have been injected with hydatid fluid. Brown (1943) found an additional thermolabile antigen in mouse tissues distinct from, but related to, the Forssman antigen. (For further information about heterophile antigens, particularly in relation to polysaccharide substances, see the review by Tomcsik 1945.)

Age and Natural Antibody Production.

Excepting those passively derived from the mother, "normal" hæmolysins and hæmagglutinins are absent from the blood of new-born infants and of other very young animals, and are developed during the process of normal growth (Hirszfeld 1926, Friedberger, Bock and Furstenheim 1929). The same is apparently true of the natural antibacterial agglutinins (Kraus and Low 1899, Ludke 1905, Braun 1909, Gibson 1930; see also Mackie and Finkelstein 1928, 1930). Both Rywosch (1907) and Sherman (1919) noted that the normal hæmagglutinins of the fowl did not appear in the chick embryo until the twenty-first day, though Rywosch observed lysins of *Bact. coli* as early as the fourteenth day. In this connection it may be noted that Polk, Buddingh and Goodpasture (1938) could find no complement in the chick embryo. It appeared suddenly in the newly hatched chicken, and gradually increased with age. Observations made by Bailey (1923) add a point of considerable significance. He also noted the absence of hæmagglutinins in the young chick, and their appearance during the normal process of growth, but he also found that chickens failed to respond to immunization with foreign red cells until they had spontaneously developed some agglutinating capacity (see also Wolfe and Dilks 1948). The inability of the antibody-forming apparatus to respond effectively to an antigenic stimulus during the earliest period of life would seem to be a general rule. Thus, Blum (1932) and others have noted the failure of young infants to produce diphtheria antitoxin in response to the injection of toxoid. The antibody response of young rabbits to the injection of bacteria, erythrocytes, or of soluble protein antigens is poor (Freund 1930). Baumgartner (1934) found that production of agglutinins to *Salmonella enteritidis* given intravenously to rabbits was not maximal until maturity was reached. The response in 50-day-old rabbits was poor, and moderate at 70 days. It is also noteworthy that antibody from the younger animals had a lesser "avidity" than that from the mature rabbit. Baumgartner (1937) later observed a similar age difference in the response to ovalbumin, and showed that the combining power of the precipitins produced increased with the age of the immunized animal. Although it may be generally true that the capacity of very young animals to produce

Clearly, if each of these steps can be carried out, the evidence implicating the bacterium as the causative agent of the disease is very strong indeed.

Although in a great many cases this chain of experimental evidence can be developed, or, as sometimes said, Koch's postulates can be fulfilled, and the story is in its essentials complete, in a considerable number of diseases one or more of these steps cannot be carried out. In this connection, these experimental steps are best considered one by one.

The *first postulate* may be fulfilled in practically all cases if the term "observe" may be taken in its broad sense. Bacteria, of course, can be observed in the literal sense, but the submicroscopic filterable viruses cannot be seen with the aid of ordinary equipment. Their presence may be demonstrated, however, by animal inoculation, and it is not unreasonable to regard such a procedure as observation in a very real sense. It should be pointed out here that in the early days of bacteriology it was assumed that the bacterium under suspicion should be present only in cases of disease and not in healthy individuals. It is now well known that the corollary does not necessarily follow. A number of pathogenic bacteria, such as those causing diphtheria, typhoid fever and the like, may be present in a virulent form in healthy persons who show no clinical symptoms.

The *second postulate* is, in general, somewhat more difficult to satisfy, although in most cases a causative bacterium may be isolated and grown in pure culture. Perhaps the best known example of an organism that has not been cultivated outside the body of the host is the leprosy bacillus (see, however, p. 647), and as a consequence it cannot be said with certainty that this bacterium is responsible for the disease. The ultramicroscopic viruses have not been cultivated on lifeless media and, although these agents may be shown to proliferate in tissue culture or in the developing chick embryo (p. 850), there is no positive assurance that such cultures are "pure," i.e., that a virus is but a single entity and not a mixture of two or more viruses.

The *third postulate* is, in practice, probably the most difficult one to fulfill. The disease must be reproduced in a clinically recognizable form, a localized infection or a general septicemia is not sufficient although often suggestive. Since the most important diseases, from the anthropocentric point of view, are the diseases of human beings, it is necessary to find an experimental animal that will respond to the infection in the same or nearly the same manner as the human subject. A satisfactory experimental animal which complies with this requirement may be difficult to find, for phylogenetic relations are not necessarily correlated with susceptibility; monkeys, chimpanzees and the like are not, in general, better experimental animals than rabbits, guinea pigs, etc. The importance of the experimental animals to the study of an infectious disease is obvious, epidemic influenza, for example, in spite of the tremendous amount of concerted study which followed the 1918 epidemic, was but poorly understood until it was discovered (1933) that the disease could be reproduced in the ferret. The difficulties sometimes encountered in the experimental reproduction of a disease very likely stem in part from the adaptation of the bacterium to a parasitic mode of existence in conjunction with a particular host species.

The *fourth postulate* generally offers no difficulties if the preceding three

This conclusion does not, however, apply to all kinds of natural antibodies. Though the greater part of the evidence bearing on this problem has been obtained by studies of the kind outlined above, some of it has emerged from surveys of the normal antibodies present in the sera of human groups living under different environmental conditions. Thus Silverthorne (1936) determined the nasopharyngeal carriage of meningococci in a group of human subjects, and found a high degree of correlation between the bactericidal capacity of the blood for meningococci and their presence in the nasopharynx. It has sometimes been possible to correlate the results of such surveys with the associated epidemiological records, as in the studies on the distribution of diphtheria, or scarlatinal antitoxin referred to above (see, however, Peters 1940); and it has been shown quite clearly that the frequency of natural agglutinins for a particular bacterium, among a random sample of the human population living in a particular locality, is closely associated with the frequency of infections due to that bacterium in that locality. Examples are provided in the epidemiology of enteric infection (Chapter 69), of undulant fever (Chapter 75), and of certain virus diseases (Chapter 87 and 88).

A few surveys of a similar kind have been made in laboratory animals. Thus Bailey (1927) examined 81 rabbits taken from a stock in which cases of snuffles were occurring due to *Pasteurella leipsetica*. This organism was isolated from the nose, or from abscesses in three rabbits with acute snuffles, nine with chronic snuffles, three with suppurative lesions, and six with no symptoms of infection; all had agglutinins and complement-fixing antibodies in the serum. On the other hand, ten rabbits with no symptoms of infection and no detectable *Past. leipsetica* in the nares had no serum antibody. *Past. leipsetica* was instilled into the nose of five of these animals. All became symptomless carriers of the organism, and antibody appeared in the serum during the succeeding three months.

There is then no doubt that the members of a herd, or population, submitted to a constant or recurrent risk of infection with a particular bacterium will tend to form antibodies acting on that particular organism in response to the stimuli provided by infection, whether manifest or latent; and the natural working of this mechanism will certainly play a large part in determining the frequency distribution of the antibodies concerned.

We must then accept the view that the naturally occurring antibacterial sensitizers, and perhaps also the natural antitoxins, may owe their origin to any one of four mechanisms: actual infection with the corresponding bacterium; infection with some other organism that shares a common antigenic component; the entrance to the tissues *via* the intestinal tract, or possibly by other routes, of antigenic material capable of stimulating the production of an antibody with the active group in question, or the formation of such antibodies as a by-product in the normal functioning of the antibody-forming apparatus altogether apart from any specific external stimulus.

The Immunological Significance of the Natural Antibacterial Antibodies.

Do naturally occurring antibodies of the type considered above confer a relative immunity to the risk of natural infection, analogous to that conferred by the natural antitoxins? The evidence available does not allow of any but the most tentative answer. So far as it goes it suggests that there is sometimes a relation between the presence in the blood of a particular antibacterial sensitizer and a relatively high resistance to the corresponding bacterium; but that this relation

can be satisfied. Its importance should, however, not be minimized, for the presence of the microorganism in the experimentally infected animal is indicative of its proliferation and invasion of the host tissues.

A fifth postulate is sometimes added to the original four, namely: the injection of the products of a bacterium should give rise to the clinical symptoms of the disease. This postulate is applicable to those organisms which form soluble or exotoxins, such as the diphtheria and tetanus bacilli, but it is not of general significance in the incrimination of a bacterium as a cause of disease.

As indicated above, not infrequently one or more of these postulates cannot, or has not, been satisfied with respect to a given disease. The question then arises as to whether the suspected microorganism may be held responsible for the disease on the basis of only partial compliance with Koch's postulates. There is, unfortunately, no general answer to this; each case must be considered on its own merits. In some diseases, such as leprosy, the actual evidence consists in the observation of an association of a particular bacterium with a certain clinical syndrome and pathology. Whether the association may be interpreted in terms of causality is, of course, quite uncertain and consequently the etiology of leprosy is, as noted above, not definitely known. The absence of other possible etiologic agents may be regarded as favorable, though weak, ancillary evidence, and *Mycobacterium leprae* is generally, though tentatively, considered to be the cause of this disease.

In other cases indirect evidence assumes a more important position; in that of the virus diseases, for example, while there is no absolute assurance that a tissue culture represents a pure culture of virus, the homogeneity of the infective agent is rendered highly probable by facts such as the immunological relation existing among strains of a virus (e.g., influenza or poliomyelitis) and the relative constancy of the epidemiology and pathology of the disease. The inability to isolate a filterable virus in "pure culture," then, is not a serious deterrent to the implication of these agents in the causation of disease.

The case of typhoid fever is somewhat different, for here, although the organism may be grown in pure culture, the clinical picture of the disease cannot be reproduced in the laboratory animal. Indirect evidence such as the epidemiology of the disease, the undoubted efficacy of immunization with killed suspensions of the typhoid bacillus in pure culture, etc., is so strong that the disease may be regarded as almost certainly caused by this microorganism, even in the absence of the inadvertent laboratory infections of human beings which have supplied the missing link in the chain of evidence.

It is clear, then, that while the fulfillment of Koch's postulates is, in general, essential to the proof of the bacterial etiology of a disease, in some instances in which a part of the necessary direct evidence is lacking the weight of ancillary evidence may be sufficient to make the postulated causal relation highly probable or, occasionally, practically certain. It may be noted at this point that the logical processes contained in Koch's postulates are by no means confined to the study of infectious disease, the responsibility for a given fermentation, for nitrogen fixation, etc., is fixed upon a particular microorganism by essentially the same logical development of experimental evidence.

Even though a bacterium has been shown to be pathogenic, i.e., capable of producing disease, the outcome of a chance contact between such a micro-

species are relatively susceptible to infection with some of these *Salmonella* spp (Lovell 1934). A particularly striking example of this kind of discrepancy is afforded by the observation that the great majority of normal horse sera agglutinate the glanders bacillus to high titre, though glanders is bacteriologically a disease of equine animals (see Wilson 1934).

SUMMARY

(1) Antibodies of various kinds—antitoxins, agglutinins, bactericidal antibodies and so on—are frequently found in the serum of normal men and animals. The origin of these naturally occurring antibodies is still a matter in dispute; but it seems possible that they may arise in several different ways.

(2) The new-born animal, when born of a naturally immune mother, is endowed with a congenital passive immunity, due to the uterine transference of specific antibodies from the maternal blood to the foetus, or transference to the new-born animal by way of the colostrum during the early days of suckling. This, like other types of passive immunity, is of relatively short duration.

(3) Young animals from whose blood these congenitally acquired antibodies have disappeared and young animals in whom they are not present at birth often develop antibodies with advancing years.

(4) This production of antibodies is dependent on the activity of an antibody-forming apparatus that is imperfectly developed at birth, but reaches functional maturity at a relatively early period of life.

(5) There is insufficient evidence to decide whether certain natural antibodies—like the normal hæmagglutinins and hæmolysins which distinguish one animal species from another, and different varieties within a species—are produced without any external antigenic stimulus. The genetic evidence for an exclusively intrinsic determination of these antibodies is suggestive, but it is not conclusive and our biochemical insight into the processes of such determination is negligible. On the other hand, our ignorance of all but a few of the undoubtedly numerous antigenic hazards to which a mammal is subject makes it difficult to deny the existence of an external antigenic stimulus in cases where no such stimulus has been discovered.

It remains possible that certain of the antibodies acting on bacteria or their products may be formed by a process of normal serogenesis, determined ultimately by genetic factors.

(6) The more commonly accepted view is that these antibodies arise as the result of the response of the antibody-forming apparatus to external environmental stimuli, and that such stimuli usually consist of overt or latent infections with the bacterium in question. This view is particularly well established in relation to natural antitoxic immunity against diseases like diphtheria and scarlet fever.

(7) In the case of specific antibacterial immunity there are greater difficulties in accepting this hypothesis in its entirety. Samples of sera collected from a given animal species may contain antibodies active against a large number of different bacteria, and it is difficult to believe that a single animal can have been infected with so many different organisms, some of which are not known to be natural parasites of the species to which it belongs. There are, however, good reasons for believing that some at least of the agglutinins or other antibodies found

organism and a prospective host is variable. The result of this contact may be negative with no clinically apparent departure from the normal physiological state regarded as health, or obvious disease of varying degree of severity may ensue. The nature of the outcome is dependent upon the interaction of two factors, the virulence of the organism and the resistance of the host. Both virulence and resistance are vague terms which express a combined effect of a variety of component factors. Some of these are known in each case, although the manner in which they function is generally not well understood, and there are undoubtedly many more which are unknown and possibly unsuspected at the present time.

VIRULENCE

The precise meaning of the term virulence is difficult to define in an entirely satisfactory fashion. Some workers include the ability to form soluble toxins as a part of the virulence of a bacterium, toxigenic diphtheria bacilli, for example, are said to be "virulent" while the atoxigenic diphtheroids are regarded as "avirulent." Others assume virulence to be synonymous with invasiveness, the ability of a microorganism to invade the tissues of the host. Under the circumstances it is perhaps best to disregard these more subtle distinctions and to define virulence as the ability of a bacterium to produce disease, thereby making virulence and pathogenicity synonymous.

The Measurement of Virulence. By definition virulence can be measured only in terms of the production of disease. In man it is usually judged on the basis of case fatality rates, a highly virulent microorganism producing death in a large proportion of the infected persons, and one of low virulence only a small number of deaths. Similarly, the titration of virulence (or any lethal agent such as a toxin) in the experimental animal is based on deaths, but dosage, which is inversely related to virulence, can be varied. Thus virulence (or toxicity) may be defined as the dose which will produce the specified deaths in a specified animal.

In the earlier studies virulence was measured as the minimum lethal dose, defined as that amount of the substance to be tested which would just kill the experimental animal, and definitions of toxin units, etc., are given in terms of these limits (p. 288). In recent years it has become generally apparent, however, that an accurate measure is essentially statistical in nature. It is assumed, and not unreasonably, that the resistance of the normal animal to the lethal agent rests on a probability basis and is normally distributed, i.e., is described by the Gaussian frequency distribution. If this function is integrated, an S shaped curve is given by the plot of the integral which describes accumulated deaths plotted against dosage. The point of inflection is, of course, that dose with which 50 per cent of the animals die. This is called the *median lethal dose* or LD_{50} dose. This dose can be calculated by a relatively simple procedure¹ from the accumulated deaths from graded doses extending through the 50 per cent end point.

For purposes of comparison between, for example, normal and treated animals, determination of the LD_{50} doses allows a relatively precise measure having a standard basis. A somewhat less satisfactory but comparable pro-

cedure is that of relative survival times. A variety of other methods of analysis may be used for purely comparative purposes. For example, control and experimental death rates may be tested for statistical significance by the point binomial or fourfold table. Comparative death ratios, such as 8/10 to indicate that 8 animals died of 10 inoculated, are almost useless from the quantitative point of view.

Toxins. It is difficult if not impossible to account for the derangement of the normal physiological processes and attendant clinical symptoms of an animal suffering from an infectious disease on the basis of a purely mechanical effect of the presence of the invading bacteria in the blood or other tissues. It was early discovered that a number of the pathogenic bacteria produce poisonous substances which, when absorbed by the host, give rise to the symptoms and pathology characteristic of the particular disease. It has been pointed out previously (p. 124) that these poisonous substances or toxins fall into two categories. (a) the *soluble toxins*, *exotoxins* or *true toxins* which apparently diffuse out of the intact bacterial cell into the surrounding culture medium or tissue, and (b) the *endotoxins* which do not diffuse out of the intact bacterial cell but may be separated from it *in vitro* by mechanical disruption of the cell structure. These substances are liberated *in vivo* through destruction of the bacterial cells by the various defensive mechanisms of the host.

The soluble toxins, although not a part of the cell substance, cannot be regarded as secretions in the usual sense of the word. The rate of appearance of toxin does not, except in the case of *Clostridium welchii*, parallel the rate of growth of the culture, toxin is liberated in the greatest amounts after the phase of active growth is over and many of the cells are dead or dying. The endotoxins appear to be a part of the cell substance of bacteria containing them; organisms such as the cholera vibrio, certain of the dysentery bacilli and the like may be regarded as microorganisms whose protoplasm is toxic to the higher animals which they infect. There are a number of differences between these two types of toxins which may be summarized as follows:

Exotoxins

- (1) Occur outside the bacterial cell
- (2) Poisons of extremely high potency.
- (3) Excellent antigens which give antiserum of higher titer.
- (4) Combine with antibody according to the law of multiple proportions.
- (5) Protein in nature.
- (6) Thermolabile.
- (7) Destroyed by proteolytic enzymes.
- (8) Detoxified by formaldehyde.

Endotoxins

- (1) Intracellular in the intact cell.
- (2) Low potency.
- (3) Poor antigens, antiserum of low potency.
- (4) Do not combine in multiple proportions. ✓
- (5) Some are proteins but some are glucolipoids. ✓
- (6) Thermostable.
- (7) Resistant to the action of proteolytic enzymes
- (8) Toxicity not affected by formaldehyde.

These differences are by no means absolute, and the listing of them represents a generalization to which there are a number of exceptions, as will appear. Consequently, the identification of a toxin as an exo- or endotoxin can be made, not on the basis of a single property, but only on the aggregate of the properties it exhibits. Even when all its properties are taken into consideration, a given

toxin, such as the Shiga dysentery bacillus toxin, for example, may occupy an anomalous position.

The soluble bacterial toxins are, by a comfortable margin, the most potent poisons known, only the vegetable poisons, ricin and abrin, approach them in potency. The most potent of the soluble toxins are those formed by *Clostridium botulinum*, *Clostridium tetani* and the diphtheria bacillus. Crystalline type A botulinum toxin (p. 593) is the most potent of the bacterial toxins, the LD₅₀ for the mouse is only 4.5×10^{-9} mg. N. Type B botulinum toxin is somewhat less potent, 5 to 9×10^{-9} mg. N/LD₅₀ for the mouse, and crystalline tetanus toxin 5 to 7.5×10^{-7} mg. N/LD₅₀. Highly purified but non-crystalline preparations of diphtheria toxin kill guinea pigs in amounts of $0.4 \mu\text{g.}$ per kilo body weight. While these amounts seem fantastically small—for example the LD₅₀ of crystalline type A botulinum toxin is the equivalent of 2.1×10^7 molecules—the effective concentration in the body is much higher in that these toxins have marked affinities for certain tissues, as that of botulinum and tetanus toxins for the nervous tissue. Other toxins, such as that of *Clostridium welchii*, are much less potent, and it may require as much as 0.1 ml. of culture filtrate to kill an experimental animal. Still less potent are the endotoxins whose minimum lethal dose may be as much as one million times greater than that of a potent exotoxin. The MLD of a killed broth culture of the cholera vibrio, for example, is about 0.5 ml. for the guinea pig.

The potency of these toxins is, in general, paralleled by their efficiency as antigens. Antitoxic sera of high titer, 1 ml. of which will neutralize thousands of guinea pig MLD's, may be obtained against diphtheria toxin, but antitoxic sera prepared against endotoxins are generally of very low titer—several milliliters may be required to neutralize 1 to 5 MLD's of endotoxin. The neutralization of exotoxin by antitoxin proceeds according to the law of multiple proportions, i.e., if x units of antitoxin neutralize y units of toxin, nx units of antitoxin will neutralize ny units of toxin (see p. 288). The neutralization of endotoxin does not proceed in this orderly manner; it may be possible to protect an animal against 4 to 5 MLD's by the injection of antiserum, but if much more endotoxin is given, greater amounts of antiserum will not provide protection.

The nature of toxins, the soluble toxins in particular, has been a subject of long-continued interest.² The soluble toxins appear to be proteins; they are denatured by heat, may be salted out of solution, etc. Highly purified diphtheria toxin has been prepared by Eaton³ and by Pappenheimer⁴ and probably represents the pure toxin, the preparations appear to be homogeneous protein. Type A toxin of *Clostridium botulinum* has been prepared in crystalline form by Lamanna, McElroy and Eklund⁵ and by Abrams, Kegeles and Hotte.⁶ The former used an initial acid precipitation followed by shaking with chloroform and salting out with ammonium sulfate, and the latter a combination of sodium sulfate and acid precipitation. Both preparations crystallized in the form of

Cannon and Sullivan (1932) recorded experiments which they regarded as indicating the local formation of antibodies at the site of an intradermal injection. Hartley (1940) injected a mixture of vaccinia virus and an aluminium hydroxide gel intradermally in rabbits. A nodule, in which the cellular reaction was predominantly macrophage, was produced at the site of inoculation. Extracts of the 4 day-old nodules contained from 2 to 10 times as much antibody as blood or other tissue extracts (see also Orskov and Andersen 1938, DeGara and Angevine 1943). Burnet (1941), on the other hand, could find no evidence of local antibody formation in the skin of rabbits by direct injection of a variety of soluble and particulate antigens. Oakley and his colleagues (1951), making local injections of diphtheria or tetanus toxoids into various tissues of rabbits and guinea-pigs in a state of secondary responsiveness to both these antigens, obtained good evidence of the formation, in fat and muscle and sometimes in skin, of antitoxin specific for the toxoid injected into the site.

Certain facts indicate, though they do not prove, the formation of antibody at or near the mucosal surfaces of the respiratory, alimentary and genito-urinary tracts. Thus Walsh and Cannon (1938) found, after intraperitoneal antigen, an even distribution of salmonella agglutinins in the nasal mucosa, lung and spleen, with a tissue : serum ratio of 1:10. After intranasal instillation of antigen, there was proportionately more antibody in the nasal mucosa. Moreover, when different antigens were given by the two routes, the proportion of antibody to the "intranasal" antigen in terms of serum antibody was higher in the nasal mucosa than in the spleen; and that of antibody to the "splenic" antigen was higher in the spleen than in the nasal mucosa.

Antibody occurs in the faeces. In guinea-pigs with experimental *V. cholerae* enteritis, antibody to the vibrio appears in the lumen of the gut before it is detectable in the serum (see Koshland 1953), and the varying ratios of antibody in serum and faeces of animals immunized with mixtures of different dysentery bacillus antigens (Barksdale and Ghosh 1951) is also consistent with a localized, and perhaps alimentary, origin of faecal antibody. Naylor and Caldwell (1953) record high urinary titres of agglutinins, not associated with high blood titres, in Egyptians with salmonella infections confined to the urinary bladder; and Kerr and Robertson (1953) found trichomonas agglutinins in uterine mucus, but not in the serum, of cows experimentally infected *in utero* with *T. fetus*.

The Rôle of the Reticulo-Endothelial System in the Formation of Antibodies.

We discussed in Chapter 17 the mechanism by which large particles like bacteria or red blood cells, or colloidal solutions of dye, are cleared from the blood stream after their intravenous injection and taken up in the phagocytic cells of the reticulo-endothelial system. Since many of these particles contain antigen, any consideration of the site of antibody formation must include the R.E. cells. It is economical of hypotheses to assume that the cells which capture the antigen also produce the antibody, and on that basis much of the earlier work was done.

Pfeiffer and Marx (1898) stated that in rabbits, which were undergoing immunization against cholera vibrios, bacterial antibodies might be present in the spleen, the bone marrow, and perhaps the lungs, in higher concentration than in the blood (see also Tsurumi and Kohda 1913, Cary 1922).

The removal, by splenectomy or inactivation, of the substantial amount of the reticulo-endothelial tissue present in the spleen affects antibody production. Deutsch (1899) recorded that splenectomy before the injection of typhoid bacilli into guinea-pigs had little effect on subsequent antibody production, but when carried out 3 to 5 days after the injection it led to a significant decrease. He also observed that, when the spleen was extirpated from a recently immunized guinea-pig and transferred to the peritoneum of a normal guinea-pig, anti-typhoid agglutinins appeared in the blood of the latter though to a relatively low titre. Similar results, both of diminished antibody production with

needles and were pure protein, having the properties of globulin and a molecular weight of about 1×10^6 . Type B botulinum toxin has been prepared as a pure homogeneous protein, though not crystallized, by Lamanna and Glassman.⁷ Tetanus toxin has been prepared in crystalline form by Pillemer, Wittler and Grossberg⁸ by methanol precipitation in the cold and similarly appears to be pure protein. These results definitely establish the protein nature of at least these bacterial exotoxins.

With the exception of botulinum toxin, the soluble toxins are destroyed by proteolytic enzymes; botulinum toxin is, therefore, the only toxin which is effective when given by mouth. There is no chemical evidence which explains, even in part, the toxicity of these substances; these proteins do not seem to differ in any essential respect from bland proteins, such as egg albumin. The amino acid composition of crystalline type A botulinum toxin, for example, is in no way unusual. It has been suspected that toxicity might be a property of a prosthetic group attached to the protein molecule, but this appears not to be true; the balance of evidence indicates that the toxicity is a property of the structure of the toxin molecule, possibly of the arrangement of the constituent amino acid molecules in the protein.

Evidence as to the mode of action of the bacterial exotoxins is, however, beginning to accumulate. The α toxin of *Clostridium welchii* is a lecithinase and the enzymatic activity accounts in large part for the hemolytic and other toxic properties of this substance. The Welch bacillus also produces a collagenase or κ toxin which, by attacking muscle collagen, may be at least partially responsible for the pulping of muscle seen in human gangrene. Pappenheimer⁹ has reported evidence which strongly suggests that diphtheria toxin may represent the protein moiety of an iron-containing respiratory enzyme, formed in abundance when the bacilli are grown in the presence of minimal amounts of iron; possibly its toxicity may be due to a competitive inhibition of respiratory enzymes of the host (p. 153). The mode of action of neurotoxins such as tetanus toxin is not yet understood.

The discovery that the toxic qualities of the soluble toxins are destroyed by treatment with formaldehyde which, at the same time, leaves the antigenic and antitoxin-combining properties of the toxin unimpaired, has been of the greatest practical importance in immunization procedures. Toxin so treated is called *toxoid* or *anatoxin*. It might be supposed that this observation would throw some light on the nature of the toxicity of these substances since formaldehyde is known to block amino groups—a fact taken advantage of in Sørensen's formal titration of amino acids. Analysis of the formaldehyde-protein derivatives indicates that the aldehyde combines with primary amino and primary amide groups, but not with secondary amide or phenolic groups. Because of the effect of formaldehyde on toxicity and the results of detoxification with ketene and phenyl isocyanate, some workers have supposed that the free amino groups of the toxin molecule, such as the ϵ -amino group of lysine, are intimately associated with toxicity, but the evidence for this is by no means complete.

Frankel and Grunenberg 1924, Ross 1926). Such discrepancies need cause no surprise. In a system of cells so widely distributed throughout the body, the effectiveness of any method of blockade must vary according to the experimental conditions. Blockade that falls short of completeness may, as some authors have suggested (Standenath 1923), stimulate rather than depress.

Other methods of injuring or disabling the cells of the reticulo-endothelial system have been used in attempts to study the part played by these cells in antibody production—the effect of X-irradiation (Benjamin and Sluka 1908, Hektoen 1915, 1918, 1920), of thorium X (Hektoen and Corper 1920), and of radium emanation (Hektoen and Corper 1922), of benzene (Rusk 1914, Simonds and Jones 1915, Hektoen 1916a), of toluene (Hektoen 1916b, Weaver *et al.* 1913), of dichloroethyl sulphide (mustard gas) (Hektoen and Corper 1921), and of trichloroethylamine (nitrogen mustard) (Philips *et al.* 1947). The results of these experiments, taken as a whole, lend support to the view that any procedure which severely injures the cells of the reticulo-endothelial system will substantially, and sometimes completely, inhibit the formation of antibodies. The time relation of the effect of X-rays is instructive. The results of Benjamin and Sluka (1908) indicated that depression of antibody response was less in animals irradiated four days before instead of immediately after the injection of antigen. Subsequent work (see, *e.g.*, Craddock and Lawrence 1948, Clemmensen and Andersen 1948, Kohn 1951, and the review of Taliaferro 1951) has in general confirmed the refractoriness of the immune response, once antibody formation has begun, to doses of X-rays that damage such components of the R.E. system as the bone marrow, lymphatic tissues and spleen. Taliaferro and his colleagues (1952) distinguished between a moderate general effect, perhaps due to a non-specific depression of protein synthesis, manifested by a retardation of antibody production, and a strong inhibitory effect induced by irradiation from 12 hours to 7 days after injection of antigen. There was no inhibition, however, when antigen was given either before or up to six hours after irradiation, suggesting that only the phase of uptake of antigen or its early katabolism by the tissues was radiation-sensitive. The phenomenon was also described by Dixon and his colleagues (1952) who deduced that, because the antibody formed in X-irradiated animals is indistinguishable from that in normal animals, the radiation-resistant cells are the site of antibody formation (Maurer *et al.* 1953).

These studies point to the participation of the R.E. system in antibody formation; but, owing to the radiation sensitivity of much of the lymphoid-macrophage system (see Chapter 47) to the doses of X-rays usually employed, they do not unequivocally indicate any one system.

There is little doubt that large-particle antigens are first taken up in the phagocytic macrophages of the R.E. system, and that the immediate fate of soluble antigens is similar; but in neither instance are these cells the sole depository of the antigen. Using a blue antigenic azo-protein in mice, Kruse and McMaster (1949) found the antigen in the cytoplasm of the R.E. cells, especially in cells of the liver and in the sinus and reticular cells of the lymph nodes. Coons and his colleagues devised an elegant immunochemical technique for the detection of antigen in cells by treating sections of tissue with specific antibody to which a fluorescent dye had been attached. On intravenous injection, both bacterial polysaccharide and serum protein antigens were found to be localized in the R.E. cells, where their concentration gradually increased, and in the parenchymatous cells of the liver, in the cells lining the renal tubules, in the capillary endothelium and in connective tissue cells. They were also found in low concentration in the lymphocytes and the lymphoid cells of the lymph nodes and spleen. Though the protein antigens disappeared within a few days and the polysaccharides after several months, they persisted longest and were most abundant in the R.E. cells of the liver, spleen and lymph nodes (Coons and Kaplan 1950, Kaplan *et al.* 1950, Hill *et al.* 1950, Coons *et al.* 1951).

In this connection we may note that Sabin (1939) attempted to correlate the disappearance of a coloured azo-dye protein antigen from the reticulo-endothelial cells of the rabbit with the antibody levels found in the serum. Her results suggested a connection between

The endotoxins are, in general, much more resistant to heat and to the proteolytic enzymes than are the soluble toxins. Many require heating to 80°–100° C. for one hour, and an endotoxin isolated from the meningococcus requires one hour at 120° C. for destruction; in contrast, the most resistant of the soluble toxins, botulinum toxin, is destroyed by exposure to 80° C. for ten minutes. Some of the endotoxins are destroyed by the proteolytic enzymes, but others appear to be immune to the action of these ferments. Similarly, formaldehyde has little or no effect on the majority of the endotoxins.

Some of the endotoxins may be protein, and it is thought by some that these substances are not toxic *per se* but are broken down in the animal body, either in the cells or body fluids, to toxic split products. The endotoxins of the enteric bacilli have been investigated in some detail and have been found to be polysaccharide-lipid-polypeptide complexes. The complex is broken down by mild acid hydrolysis and the toxicity disappears, though in some instances the lipid fraction may retain a small degree of toxicity. There is also some evidence that the endotoxin of the cholera vibrio is closely associated with a phospholipid fraction of the cell. Substances such as these would not, of course, be affected by formaldehyde or proteolytic enzymes.

Following the injection of exo- or endotoxins, a period of incubation elapses before symptoms of intoxication appear. This incubation period may be very short or may extend to thirty-six or forty-eight hours or longer. The usual incubation period of tetanus toxin is thirty-six hours but it may be reduced to thirty five to sixty minutes by the injection of very large amounts, 500,000 MLD, of crystalline toxin. It is sometimes stated that endotoxins have no incubation period, thereby differing from the exotoxins, but this is not generally true.

The pharmacological action of the soluble toxins resembles that of the vegetable alkaloids and is sometimes quite definite and characteristic for each toxin. Diphtheria toxin, for example, produces degeneration of the heart muscles, kidneys and liver and the hemorrhagic reaction in the adrenals which is a highly characteristic postmortem finding in the guinea pig. A part of tetanus toxin (tetanospasmin) has an affinity for the motor nerves. On the other hand, the symptoms and pathology resulting from administration of the endotoxins are not at all characteristic although minor distinctions have been reported. Animals inoculated with lethal doses of these substances usually show dyspnea, diarrhea and, in some cases, flaccid paralysis of the posterior extremities, become progressively weaker and finally die without having exhibited symptoms that might be regarded as characteristic of a particular endotoxin. The histopathology often indicates that the toxin exerts its effect on the blood vessels, damage to which results in degenerative changes in the tissue supplied. It has also been found¹⁰ that these substances affect the carbohydrate metabolism of the host, decreasing tissue glycogen, lactic acid and pyruvic acid, and specifically inhibiting succinic dehydrogenase, the relation of these changes to observed pathology is, however, not clear.

As has already been suggested, the bacterial toxins are not unique. Substances closely resembling the soluble toxins occur in the seeds of some of the higher plants and in the secretions of certain animals. Among the better

¹⁰ Kun and Müller. Proc. Soc. Exp. Biol. Med. 1948, 67,221.

The lymphocyte and antibody formation.—Ehrlich and Harris (1942) applied the double-antigen technique of McMaster and Hudack to the rabbit leg, with typhoid bacilli, sheep erythrocytes, and ovalbumin as antigens; in their hands the antibody maxima in efferent lymph and in the lymph nodes slightly preceded the maxima in germinal centres, whose increased numbers persisted some time after antibody levels were declining. The rise in antibody content of lymph from an immunized lymph node was accompanied by a rise in the cellular content. The cells, which were predominantly lymphocytes, contained substantially more antibody than the lymph and, since normal lymphocytes did not appear to absorb antibody, Harris and his colleagues (1945) suggested that the lymphocyte was the site of antibody formation. Similar results were obtained with two serologically distinct strains of influenza virus (Harris and Harris 1949b). Formation of antibody in the lymph nodes of the rabbit and horse was demonstrated by Oakley, Warrack and Batty (1949) after the local injection of secondary stimulating doses of diphtheria and tetanus toxoids; in horses, the nodes continued to produce antitoxin for several months. Habel and his colleagues (1949), on the other hand, found no experimental evidence of antibody formation in lymph nodes, or of transport of antibody by lymphocytes (but see Harris and Harris 1950).

The hypothesis of the lymphocyte as the site of antibody synthesis is in accord with the diminished antibody formation observed in animals whose lymphoid tissue as a whole is damaged or decreased by X-irradiation or nitrogen mustard (see, e.g., Schwab *et al.* 1950, Tahaferro and Tahaferro 1951) or by prolonged dosage with cortisone (Björneboe *et al.* 1951, Fischel *et al.* 1952, Malkiel and Hargis 1952); but as we noted above, this evidence does not point unequivocally to any one type of cell.

Small doses of X-rays induce a fall in circulating lymphocytes, and in immunized animals they are reported to increase serum antibody titres, presumably by lysis of cells ("lympholysis") and release of contained antibodies (Dougherty and White 1947; but see Roberts and White 1951); but others have failed to elicit this effect (Fischel *et al.* 1949, de Vries 1949; see also Marshall and White 1950). Dougherty and White recorded a transient rise in circulating sheep cell agglutinins in immunized rabbits, after a lympholytic dose of various adrenocortical hormone preparations, and postulated a hormone-induced release of antibody from these cells as part of the mechanism of antibody formation. The hormone effect was observed by others in immunized rabbits and rats (Eisen *et al.* 1947, Bussard *et al.* 1950, Hammon and Novak 1950), and amphibia (Bisset 1949). Bussard and his colleagues observed proliferative changes in the transitional and plasma cells of the spleen, as well as a lymphopænia, induced by the hormone. Fischel, LeMay and Kabat (1949) found no evidence of antibody release by adrenocorticotrophin (see also Havens *et al.* 1952). The view that antibody production is necessarily under hormonal regulation, or that the lymphocyte participates in regulation, either as a producer or transporter of antibody, remains to be established. In this connection we may note that, in immunized rats, the induction of lymphopænia by the administration of an anti-lymphocyte serum—a procedure presumed to destroy the lymphocytes—did not increase the circulating antibody (Woodruff *et al.* 1951); nor did the *in vivo* lysis of the lymphocytes by colchicine (Fagreu and Gormsen 1953). The presence of antibody in lymphocytes (see Harris and Harris 1950) is not consistent with the results of other experimental work (Craddock *et al.* 1949, Björneboe *et al.* 1947, Hammon and Novak 1950). Erslev (1951), for example, could find no antibody in the circulating lymphocytes of rabbits hyperimmunized with pneumococci, though the serum was rich in it. It will be realized that the evidence for the participation of the lymphocyte, as distinct from other lymphoid cells, in either the formation or the transport of antibody is both confused and contradictory. At present, the balance of the evidence is against the lymphocyte, at least as far as antibodies that can be detected by the orthodox *in vitro* techniques are concerned. The matter is, however, by no means settled. There is, moreover, a field of specific *in vitro* reactions involving antigen or hapten, but not detectable antibody, which are consistently associated with this type of cell. As we shall see in Chapter 51, certain forms of specific hypersensitivity

known toxins of plant origin (phytotoxins) are ricin (from the castor oil bean, *Ricinus communis*), abrin (from the jequirity bean, *Abrus precatorius*), and the similar substances, croton and robin. The more familiar examples of similar poisons of animal origin (zootoxins) include snake venoms, the poisons of scorpions and spiders and an actively poisonous substance present in eel blood. The chemical behavior and physiological action of these poisons are strikingly similar to those of the bacterial exotoxins. Antitoxins have been prepared against a number of these substances and the antivenins have been used with considerable success.

The "Invasiveness" of Bacteria. It was early suggested that, in addition to toxins, some of the highly virulent bacteria which invade the host tissues with great rapidity are enabled to do so by the secretion of soluble substances termed *aggressins* by Bail¹¹ and *virulins* by Rosenow.¹² Although subsequent experiment has provided evidence which strongly supports this general concept, these terms have, at present, little more than historical significance. It has been found that virulence in terms of tissue invasion and destruction of the defense mechanisms of the host by bacteria may be subdivided into a number of component factors. The more important of these are the *hemolysins* and *leucocidins* which destroy the red and white blood cells, the *coagulases* and *fibrinolysins* which influence the formation and dissolution of blood clots and a spreading factor which produces a marked increase in the permeability of the host tissues. Although some of these properties are associated with virulence, others are not so correlated and their relative importance is uncertain. It is probable that the ability of a bacterium to invade the tissues is not dependent upon any single property but rather upon a combination of properties, including both those that are known and others that are as yet unknown.

Hemolysins. A variety of bacteria produce hemolysins, substances which bring about the dissolution of the red blood cells of higher animals. The bacterial hemolysins, which are to be distinguished from the immune hemolysins formed by an animal in response to the injection of red cells of another species (p. 290), are of two types, the so-called filterable hemolysins which are extra-cellular and may be separated from the bacterial cells by filtration, and the hemolysins which are demonstrated by the cultivation of bacteria on semi-solid media containing whole blood.

The filterable hemolysins are sometimes named after the bacteria which form them, a *streptolysin*, for example, is a hemolysin produced by streptococci, and a *staphylolysin* a hemolysin of staphylococci. Hemolytic activity is demonstrated by the addition of filtrate or whole culture to a suspension of washed erythrocytes in physiological salt solution, after a period of incubation the red cells are laked and hemoglobin appears free in solution. The relation of these hemolysins to other naturally occurring hemolysins such as saponins, the hemolysins present in snake venoms and the like, is uncertain.¹³ The bacterial hemolysins appear to be proteins in nature, are inactivated by

¹¹ Bail Arch. Hyg., 1905, 52 272.

¹³ For a general discussion of hemolysis see the exhaustive monograph of Ponder *The Mammalian Red Cell and the Properties of Hemolytic Systems*. Protoplasma Monograph, No. 6, 1934.

Other cells.—There is no good evidence of liberation of antibody from polymorphonuclear leucocytes (see Fastier 1948, Walsh and Smith 1951). Girard and Murray (1954) took advantage of the increase in circulating monocytes produced by the lipid extractable from *Listeria monocytogenes* to investigate the rôle of these cells. When a high monocyte count was maintained in rabbits by this means, antibody response to the typhoid bacillus and to staphylococcus toxoid was increased. Moreover, when a predominantly monocyte pleural exudation was induced in such animals during the secondary antibody response, the cells contained more antibody than the fluid. This was not, however, evidence of antibody formation by the cells, because passively administered antibody proved to be concentrated within them.

As regards other tissues, it is noteworthy that muscle does not appear to synthesize antibody (Keppie and Macfarlane 1948). The liver, though turning out most of the plasma proteins, does not in the rat appear to synthesize globulin (Miller and Bale 1954); if this proves to be generally true, then we may exclude the Kupffer cells of the R. E. system as a major source of antibody.

The Formation of Antibodies in Tissue Cultures.—A method which offers obvious possibilities for the study of antibody formation is that of tissue culture.

Carrel and Ingebrigsten (1912) cultivated fragments from the bone marrow and lymph glands of guinea-pigs in the homologous blood plasma, and added to the cultures small amounts of red cells from the goat, against which the serum of the guinea-pig showed no lytic action. Hæmopsonins appeared in the culture on the 3rd day, as judged by direct observation of the degree of phagocytosis. Hæmolysins were detectable on the 4th day, and had increased markedly in activity on the 5th. The hæmolysins could be specifically absorbed from the fluid by the usual technique. Lüdke (1912) injected killed cultures of typhoid or dysentery bacilli into rabbits, removed fragments of the spleen or bone-marrow after 1 to 5 days, and cultivated them in homologous plasma. After 2 to 5 days' incubation he was able to detect lysins and agglutinins in the culture fluid. In a similar way he succeeded in producing hæmolysin for ox or sheep corpuscles. His results were for the most part negative when he added the antigenic materials directly to the tissue cultures. Przygode (1913, 1914), Reiter (1913) and Schulf (1926) also recorded positive results. Subsequent workers, including those we have mentioned above in the section on antibody production by plasma cells, have demonstrated antibody formation against a variety of antigens when the cultures were made from the tissues of already inoculated animals; but the results of adding the antigen after the establishment of the tissue culture *in vitro* have been uniformly negative (Meyer and Lowenthal 1928, Hwon 1937, Parker 1937, Salle and McOmie 1937, Beard and Rous 1938). The reasons for the failure of *in vitro* immunization are not apparent, though Beard and Rous, who used a pure culture of Kupffer cells from the liver, note that the cultivated cells had lost their normal *in vivo* power of ingesting antigenic particles.

Conclusions with regard to the Site of Formation of Antibodies.—Taking the evidence as a whole the conclusions to be drawn do not seem to be in doubt in spite of various discrepancies. There is ample evidence that the lymphoid element of the lymphoid-macrophage system (Chapter 47) is concerned with antibody formation. The researches of the past decade clearly indicate that an adaptive cellular response occurs *pari passu* with the antibody response, in organs which, like the spleen, are usually credited with antibody formation, and in lymph nodes, and in discrete regions of connective tissue stimulated by antigen. The site of this response varies with the route of injection of the antigen, and it is possible that the type of cell produced varies significantly with the antigenic material. The evidence implicating any particular kind of cell as the site of antibody synthesis is largely circumstantial, and although refinements of technique have led to a

heating (55° C. for thirty minutes), and are antigenic, *i.e.*, when injected into animals they stimulate the formation of antihemolysins.

That hemolytic activity is a property of a group of substances of bacterial origin rather than of a single substance formed by a number of bacterial species is indicated not only by differences in immunological specificity but also by the varied properties of the activity. Many hemolysins, for example, are oxygen-stable, but some, produced by the pneumococcus and certain strains of streptococci, are oxygen sensitive, *i.e.*, they are active in the reduced form but inactive in the oxidized form, the oxidation-reduction being reversible at low temperatures.¹⁴ Hemolysins further differ from one another in their heat and acid resistance and in the incubation time which precedes visible laking of the red cells. Differences in their activity on the erythrocytes of various species of higher animals may be marked, a given hemolysin, for instance, may

Fig. 28. "Hot-cold" hemolysis. *Staphylococcus aureus* on sheep blood agar. Produced by holding the plate alternately at incubator and refrigerator temperature. The small clear zones are produced in the incubator by the α lysin and the large zones in the refrigerator by the β lysin.

lyse sheep cells but not rabbit cells. In general the cells of the animal species from which a bacterium is isolated are more sensitive to its hemolysins than are the cells of other animal species.

A single bacterial strain may form more than one hemolysin. Certain strains of staphylococci form at least two hemolysins, one acting on both α and β and the other β only.¹⁵

The former is termed α lysin and the latter β lysin. The action of both can be shown in culture on sheep blood agar, the α lysin producing a zone of complete clearing on twenty four hours' incubation and the β lysin producing a zone of darkening which becomes lighter and clear on subsequent refrigeration of the plate.¹⁶ This phenomenon is illustrated in Fig. 28

The minute dose of 10,000 bacilli per kilo. body weight, administered to rabbits, results in no detectable agglutinins. With ten times the dose we pass the threshold and obtain an average titre of 1/330. Over the range 10^5 to 10^8 bacilli a thousandfold increase in dose results in about a tenfold increase in titre—the critical student glancing at the numbers in the second column will not place too much reliance on the mean values recorded in the third. When we increase our dose still further we shall get still higher titres; but we shall be reaching the point where our inoculum attains an appreciable toxicity, and we shall, apart from this, be subject to the law of diminishing returns. However high we push our dose, up to the limit that will kill our rabbit, we are unlikely, after any single inoculation, to reach a titre of more than 1/10,000–1/20,000.

In general, there is a minimal threshold value, below which no response is obtained. Above this value the titre attained varies with the dose administered, but in such a way that the increase in titre is relatively much smaller than the increase in dose required to produce it. Eventually a point is reached at which further increase in dose results in little or no increase in antibody production.

TABLE 80

10^4	4	0 ¹

¹ = no agglutination at a dilution of 1/4.

Not all antigens induce this kind of dosage response. For example, even very small doses of the acetyl polysaccharide on the Type I pneumococcus call forth the production of antibodies (Avery and Goebel 1933, Enders and Wu 1934). Downie (1937) found that an effective immunizing dose in mice lay between 1.0 and 0.01 μg .; larger doses, of 100 or 1,000 μg ., proved to be ineffective.

Immunological paralysis—Massive doses of antigen may completely paralyse the response of the antibody-forming apparatus. We discussed in Chapter 49 Felton's demonstration of such an immunological paralysis in mice given an overwhelming dose of pneumococcal polysaccharide—enough to remain for a long time detectable in the tissues. The analogous phenomenon, of specific induced tolerance, is elicited by the introduction of antigen into the foetal mouse or chick before its capacity to synthesize antibody has matured. With maturation of this capacity after birth, the animal is indifferent to stimuli by the antigen employed (Billingham *et al.* 1953).

Variations in Response to Different Antigens.—Fig. 253 shows the effect of injecting into an animal (a dog) a particular antigen (rat corpuscles) against which it possesses a normal antibody (haemagglutinin). The immediate effect of the injection is to cause a fall in the normal antibody titre, followed by a rapid rise of the type depicted in Fig. 252. This *negative phase* is a characteristic result of injecting any large amount of antigen into an animal that possesses the corresponding antibody in its circulating blood.

Similarly, some strains of streptococci produce two hemolysins, one of which is relatively heat-stable but oxygen-sensitive and the other oxygen-stable but heat-sensitive.¹⁴ It has been shown by Bernheimer¹⁷ that streptolysin O, the oxygen-labile hemolysin, has a toxic action on the isolated frog heart. This cardiotoxic action is of particular interest in that it appears only on second application following a first or sensitizing application which releases an inhibitor and leaves the tissue susceptible to the action of the cardiotoxin.

The production of hemolysins is favored by inclusion of serum in the broth in which the microorganisms are cultured, and it is of some interest that the activity of the hemolysin formed in such media is most marked on the red cells of the animal species from which the serum was derived.¹⁸ The hemolytic activity of a culture may be transitory, probably because of inactivation of formed hemolysin. Some hemolysins lose their activity when incubated at 37° C. for two hours or more; for example, de Kruif and Ireland¹⁴ found a maximum hemolytic titer after eight hours' incubation of streptococcus cultures which declined rapidly thereafter so that in many cases no activity could be detected in filtrates of fourteen-hour cultures.

Blood-Plate Hemolysis. The colonies of some bacterial species on blood agar produce visible changes in the medium immediately surrounding the colony which are termed "hemolysis." Two general types of change are observed, one designated as α or green hemolysis, in which the bacterial colony is surrounded by a zone of greenish discoloration, and the other, β -hemolysis, in which the zone around the colony is clear and uncolored, in contrast with the red opacity of the medium. According to Brown¹⁹ the zone of discoloration of α -hemolysis is surrounded by a very narrow clear zone, but this is not apparent except upon careful examination. Microscopic examination of the green zone shows the presence of many discolored corpuscles, but in β -hemolytic zones corpuscles cannot be found.

The relation between blood-plate hemolysis and the filterable hemolysins is usually regarded as uncertain, for, although microorganisms hemolytic on blood plates frequently do not appear to produce filterable hemolysin, some workers maintain that, since filterable hemolysins are difficult to demonstrate, failure to find them is not significant. It would appear that the processes involved are different, in the case of the filterable hemolysins the permeability of the red cell is altered and the hemoglobin escapes into the surrounding fluid, while in blood-plate hemolysis the pigment is broken down to green or colorless compounds. In the case of the cholera vibrio the two processes have been sharply differentiated,²⁰ since the identification of this organism is dependent in part on the hemolysis of goat erythrocytes in suspension (Grieg test), though the true cholera vibrio is negative to this test, some strains show hemolysis on blood agar plates. Van Loghem has distinguished between the hemolysis of goat erythrocyte suspensions and what he has termed hemodigestion on blood agar. On the other hand, there appears to be a close association between β -hemolysis and streptolysin O. Green hemolysis was formerly thought

and Hektoen and Boor (1931), on the other hand, have recorded results which indicate a far less restricted range of activity. The latter observers immunized rabbits

FIG. 255.

Antitoxin production in the horse: showing difference between primary and secondary response. (After Glenny and Südmersen.)

and Waddington 1925, Glenny and Waddington 1926, 1928) makes it clear that the simultaneous injection of several antigens may considerably reduce the titre of antitoxin obtained. It seems probable, as Glenny suggests, that this "crowding-out" effect is particularly prone to occur when any one antigen is present in great excess. In guinea-pigs inoculated with tetanus toxoid mixed with a second antigen—either diphtheria toxoid or a typhoid vaccine—Barr and Llewellyn-Jones (1953) demonstrated a crowding-out of the tetanus antitoxin response when the animals already had a basic immunity to the second antigen, as a result of which the second antigen induced a substantial secondary response that apparently occupied most of the animals' capacity to synthesize antibody (see also Barr and Glenny 1952).

Bjorneboe (1941, 1943, 1945) immunized rabbits with vaccines containing from one to eight types of pneumococcus, which were given every second day for 8 months; the antibody production per type was the same for mixtures up to three types, and became progressively weaker as the number of antigens increased. When the "ceiling" values of serum antibody were attained, all the serum globulin appeared to consist of antibody. With hyperimmunization the globulins might rise to over seven times the normal value; this was accompanied by an apparently compensating decrease in serum albumin. The separate antitoxic response of rabbits to mixtures of diphtheria, tetanus and staphylococcal toxoids (Ramon and Richou 1940) and of diphtheria and staphylococcal toxoids given intranasally (Sato and Kodama 1940) was found to be similar to that following injections of the single antigens.

In man, a combination of two or more antigens is reported by some to have a synergic effect, each antigen being more effective in combination than alone. For example, synergic effects are recorded for mixtures of diphtheria and tetanus toxoids, with and without typhoid vaccines (Sacquepée, Pilod and Jude 1936a, b); for staphylococcal and diphtheria toxoids (Kodama, Sato and Hata 1940); for tetanus toxoid and typhoid vaccines (Ramon 1936, Maclean and Holt 1940; see also Grasset and Girdwood 1940, Fraser *et al.* 1943); for diphtheria and tetanus toxoids (Bigler and Werner 1941), and for these two toxoids

by repeated intravenous injections of mixtures containing large numbers of different antigens, each in a relatively pure state. These included hæmoglobin from the ox, cat, dog, hog, horse, man, sheep and turkey, horse pseudoglobulin, serum albumin from chicken and man, egg albumin and other constituents. One of the mixtures contained 14 different antigenic constituents, the other 35. Precipitins were produced against almost all the antigens injected, and in most cases to high titre.

In the case of antitoxins the careful work of Glenny and his colleagues (Glenny 1925a, Glenny, Hopkins

to be due to the formation of methemoglobin and associated with the formation of hydrogen peroxide, but it has been found²¹ that the green substance is an iron-containing derivative of hemoglobin very possibly formed by reduction. The mechanism of β -hemolysis is not well known, but in the case of staphylococcal hemolysins, the hemoglobin is not destroyed; according to Christie and Graydon¹⁶ the clearing around the colony is due to migration of the liberated hemoglobin. As in the case of the filterable hemolysins, hemolysis on blood agar is frequently species-specific; a higher proportion of bacterial strains will show hemolysis on blood from one animal species and not on that of another.

The relation of ability to form hemolysin and virulence is obscure. Although among some of the parasitic bacteria such as streptococci and staphylococci, virulence is associated with hemolytic activity, a number of saprophytic bacteria also produce hemolysins. On the other hand, it has been reported that in staphylococcus infections of the udder, the hemolytic strains are much more irritating than the non-hemolytic organisms. It might be expected that infection with actively hemolytic bacteria would be accompanied by anemia and hemoglobinuria but this is not the case, as a rule; infections with *Clostridium welchii*, however, are frequently characterized by a gross blood destruction and consequent severe anemia and jaundice which is due to the continuous release of the hemolytic α -toxin (p. 581). It is also not unlikely that hemolysins may exhibit toxicities other than that of the lysis of erythrocytes, as, for example, in the case of the cardiotoxic action of streptolysin O noted above.

Leucocidins. A number of bacteria, notably staphylococci, streptococci and pneumococci, form leucocidins, substances which kill and, in some cases, lyse, polymorphonuclear leucocytes. The death of the leucocytes results in the inability of these cells to reduce methylene blue, a phenomenon made use of by Neisser and Wechsberg²² and others to demonstrate the activity of these substances. A direct microscopic method has been introduced²³ which has shed some light on the effect of these substances on the white blood cell. Human and rabbit leucocytes in contact with leucocidin become spherical, the nuclei fragment and the cells may, with some leucocidins, eventually burst or, with others, remain intact.

The amount of leucocidin produced by one bacterial species may vary widely from one strain to another, and a single strain may produce more than one leucocidin. The detection of more than one leucocidin is dependent upon differences in thermostability and in the kind of leucocytes attacked, one staphylococcal leucocidin, for example, affects both rabbit and human leucocytes, while another is active only on rabbit cells. In general, the leucocidins closely resemble the filterable hemolysins in that they are antigenic, variable in their heat resistance, etc., and, in some cases, may be identical with hemolysins. The α -hemolysin of staphylococcus, for example, is a leucocidin.²⁴ They may not be strain specific; some of the staphylococcal leucocidins, for example,

²³ Valentine, Lancet, 1936, 1:526. It should be pointed out that it is claimed by some workers that the leucocidin tested by one method is not the same as that tested by the other.

²⁴ Wright: Lancet, 1936, 1:1002.

antigenic material is not limited to the production of diphtheria antitoxin, though it is particularly well marked in this case. Fig. 256 shows a similar response to an injection of horse serum in a rabbit which had previously been injected with that antigen, but whose precipitin titre had since sunk to zero.

The same holds true, in regard to the comparative titre attained, though not in regard to the prolonged induction period after the primary stimulus with large-particle antigens, such as bacteria. Table 81 sets out the primary and secondary response of rabbits to the intravenous injection of 10^5 *Salmonella paratyphi B* per kilo. body weight. It will be noted that the titres given are not the maxima attained but the average titre during the 50 days after inoculation. This value was selected because the curve of agglutinin titre after a secondary inoculation tends not only to rise higher than after a primary injection, but to remain high over a longer period.

These three are examples with protein antigens. Not all antigens stimulate a secondary response. Burnet and Freeman (1938), for example, could induce no secondary rise of antibody in rabbits primarily and secondarily stimulated by intravenous injection of Q fever rickettsiae. Heidelberger and his colleagues immunized man with the type-specific pneumococcal polysaccharides. After a

TABLE 81

SHOWING THE AVERAGE TITRE OVER A PERIOD OF 50 DAYS AFTER PRIMARY AND SECONDARY INJECTIONS INTO RABBITS OF 10^5 *Salmonella paratyphi B* PER K.B.W.

R31	91	133 "	1,230
R33	110	133 "	2,010

small primary inoculum the serum content of specific antibodies rose slowly for several weeks, remained high for 5 to 8 months, and dropped to 20-50 per cent. of this maximum value in the next 3-6 years. A secondary inoculum had little effect after eight years, except in a few subjects with a low titre of antibody, and even here the effect was slight (Heidelberger *et al.* 1946, 1950; but see Murray *et al.* 1950).

The difference between the primary and secondary response is sufficiently obvious and needs no comment. With very small doses there may be no detectable primary response, antibodies failing to appear till after the second or later injection of a bacillary suspension, as illustrated in Table 82.

Burnet (1941) has emphasized a distinguishing feature of the secondary response that is especially obvious when the stimulating dose of antigen is given intravenously. In the secondary response to staphylococcal toxoids, herpes virus and a bacteriophage, after a delay of 1 to 2 days, the antibody content of the serum increased exponentially with regard to time, until the maximum level was approached, when the rate of increase in antibody content gradually diminished to a low value. In Fig. 257, for example, where the staphylococcal antitoxin content of the serum is plotted logarithmically, the curve is practically linear from the 2nd to the 4th day (see also Holt 1951).

are immunologically similar if not identical regardless of the bacterial strain from which they are derived.²⁵

The part played by the leucocidins in the virulence of a bacterium is obscure. Theoretically, it should be of some advantage to an invading microorganism to be able to destroy these phagocytic cells and thereby break down, to some degree, the defenses of the body. The polymorphonuclear leucocytes (heterophils) are not, however, the most important cells in the phagocytic destruction of bacteria (p. 294), and the effect of these substances on the other phagocytic cells, the mononuclears, the histiocytes and others is not known. As in the case of the hemolysins, the leucocidins of bacterial origin must be differentiated from the immune leucocidins, those produced by the animal body in response to the injection of leucocytes from another species.

Coagulase²⁶ and Fibrinolysin. The formation of blood clots is accelerated by a substance, coagulase, formed by some bacteria, and the clots formed, either with or without the acceleration of this substance, may be dissolved by other substances of bacterial origin, the fibrinolysins. The production of coagulase, is, so far as present information is concerned, confined to the staphylococci for the most part, and may be causally related to the thrombi that are common in infections with these organisms. Occasional strains of other organisms such as *Pseudomonas pyocyaneus*, *Bacterium prodigiosum*, *Bacterium coli* and *Bacillus subtilis* have, however, been observed to accelerate the clotting of blood. Coagulase activity is demonstrated by the addition of bacteria to citrated or oxalated blood plasma (usually rabbit), which gels within three hours. Cell-free coagulase has, however, been prepared from plasma cultures of *Staphylococcus aureus*.²⁷ Coagulase is regarded by some as a precursor of a thrombin-like substance and requiring an activator present in some, though not all, plasmas.²⁸ Unlike coagulase, the thrombin-like substance is thermolabile. The clotting produced by coagulase is not, however, inhibited by "antithrombins" such as heparin or hirudin. The activity is not filterable and is relatively thermostable; it is only partially destroyed by exposure to 100° C. for thirty minutes. Other properties such as precipitation with alcohol and acid and ammonium sulfate and inactivation with trypsin and pepsin suggest a protein nature. Its antigenicity is uncertain. The relationship of coagulase to virulence is obscure, although it is often said that there is no association between the two. It would seem that the property of accelerating the clotting of blood might, on the one hand, be unfavorable to further invasion of the host tissues by a microorganism forming this substance, and, on the other, serve as a temporary protection against the defenses of the host. Hale and Smith²⁹ have observed that coagulase-producing staphylococci are less susceptible to phagocytosis in the presence of plasma than are coagulase-negative strains, presumably a result of coating the bacteria with a film of coagulum.

²⁵ For a general study of these substances see Todd Brit. Jour. Exp. Path., 1942, 23: 136.

²⁶ For a summary of information regarding coagulase see the review by Blair Bact. Rev., 1939, 3:97

²⁷ Lominski Nature, 1944, 154 640.

²⁸ Smith and Hale. Brit Jour Exp Path., 1944, 25:101.

²⁹ Hale and Smith Brit. Jour. Exp. Path., 1945, 26 209; *ibid.*, 1947, 28:57.

It is probable that secondary responsiveness lasts for some time after serum antibody is no longer detectable. Murray, Ofstrock and Snyder (1952) found that secondary responsiveness to typhus vaccine in man might last for 5 to 6 years.

TABLE 82

It must not be supposed that the differences between a primary and secondary response are always so clear-cut as those depicted here. The curves may, however, be regarded as giving a true picture of the kind of differences observed. It will be noted in Figs. 258 and 259 that the primary response may be quite brisk and result

FIG. 259.

Agglutinin production: response of an uninoculated person to a single injection of typhoid vaccine.

level, which varies widely with the nature of the antigen employed and the responsiveness of the animal injected, it becomes impossible to induce any further rise in the concentration of antibody in the circulating blood.

Fig 261 (p 1275) shows the effect of repeated subcutaneous injections of typhoid bacilli in a rabbit (Goldberg 1901). Each successive injection raises the agglutinin

in a high titre of agglutinins. This, for instance, is the usual experience as regards the production of H agglutinins in response to the injection of an optimal dose of flagellated bacilli.

We have seen that increases in the dose of antigen administered at a single injection are subject to the law of diminishing returns: in just the same way the repetition of injections, beyond a certain number, is usually found to produce less and less effect with each successive dose. When the titre of a particular antibody has been forced up to a certain

Fibrinolysin.³⁰ Perhaps more important to the virulence of a bacterium is the ability to dissolve formed blood clots through the agency of fibrinolysin. It has been observed that if a small amount of bacterial culture is mixed with oxalated plasma and the latter allowed to clot by the addition of calcium chloride, the fibrin clot may be dissolved within a short time as a result of bacterial activity. The activity may be titrated by determining the highest dilution that will lyse a fibrin clot in one hour at 37° C. At present it appears that the ability to bring about this lysis is confined to certain groups of streptococci, although other bacteria such as staphylococci, the plague bacillus and others have been described as fibrinolytic. Like the hemolysins, the fibrinolysins appear to exhibit some degree of specificity with respect to the source of the fibrin, streptococci isolated from human infections, for example, will lyse clotted human plasma more rapidly than plasma clots from other animals. Fibrinolysin appears to fall into the same general category as the toxins, hemolysins and the like in that it is found in culture fluid freed from bacterial cells, appears to be protein in nature, and is antigenic. Fibrinolysin is, however, distinct from these other substances; although a high correlation has been observed between the occurrence of filterable hemolysin and fibrinolysin, in many cases a bacterial strain is able to bring about the dissolution of erythrocytes but not solution of clots, and *vice versa*.

The nature of the lytic process has been of some interest, and it has been found³¹ that fibrinolysin is an activator of an inactive proteolytic enzyme or "lysin factor" present in the serum. Thus the term fibrinolysin is a misnomer, and possibly the active enzyme should be termed "plasmin." In any case, the lytic process is accompanied by an increase in amino nitrogen and other manifestations of proteolysis.

Fibrinolysin is antigenic and fibrinolysins from different strains of bacteria appear to be very similar if not identical immunologically. Antisera specifically inhibit the activity and the occurrence of anti-fibrinolysin in the serum has been useful as an indicator of past infection with fibrinolysin-positive streptococci.

It should be noted here that a number of bacteria exhibit a tendency to inhibit the clotting of plasma, a property that may be demonstrated by delaying the addition of calcium to the oxalated plasma; when calcium is added after a period of preliminary incubation, the clot fails to form. This property has been most often demonstrated with cultures in dextrose broth, and in some cases, at least, the failure of the plasma to clot is a result of the presence of lactic and other acids formed in the fermentation.

Fibrinolysin appears to be closely associated with virulence and particularly with the ability to invade the body tissues. Since one of the first reactions of the body to tissue destruction is the formation of blood clots which tend to wall off and isolate the infected region, it is not surprising that a bacterium capable of lysing these clots should show marked tendencies to extensive tissue invasion. The streptococci are among the most invasive of the pathogenic forms, and this

³⁰ See the review by Tillet. *Bact. Rev.*, 1938, 2 161.

³¹ See Christensen. *Jour. Gen. Physiol.*, 1945, 28:363, 559, Holmberg. *Arkiv Kemi Mineral. Geol.*, 1944, 17A 8.

of adjuvant substances to the antigen. With regard to the route of immunization, it is generally held that antigens in the form of large particles, like bacteria or animal erythrocytes, are most effective when given intravenously (see, for example, Marinelli 1937), whereas soluble antigens are best given into the tissues. If a soluble antigen is attached to coarsely particulate matter, it may be most effective by the intravenous route (Freund and Bonanto 1941). A probable cause of the relative inefficacy of intravenously injected soluble antigens is their rapid elimination from the body. The same factor probably diminishes the stimulus of antigens injected into the tissues, for most of the procedures that increase antigenicity appear to act by hindering the release of antigen from the injection site.

Variation in the volume of the inoculum.—The experiments of Hartley (1935) indicate that the total volume of an immunizing injection, as well as its content in antigenic material, has a significant influence on the antibody response. A series of guinea-pigs were injected with a constant dose of diphtheria toxoid made up in a total volume of 0.5 ml. or 5.0 ml. of saline. In repeated tests it was found that the animals receiving the larger volume gave a far better immunizing response. Timmerman and Brandwijk (1936*a, b*) confirmed Hartley's results. Schmitz (1938), however, repeated the test in medical students, and found no difference either in antitoxin response or in the rate at which antitoxin disappeared from the blood.

Dispersal of the inoculum through the tissues.—A stimulation of response resembling that of Hartley (1935) may be obtained by subdividing a dose of antigen into several smaller doses and injecting each into different sites in the animal. The response is greater than that produced by the whole dose administered singly (Ramon, Lemétayer *et al.* 1937, Miles and Pirie 1939).

The addition of adjuvants.—Adjuvants are usually intended for injection into the tissues, and are for the most part mildly irritant substances. Alum is one of the most widely used adjuvants. It was introduced by Glenny and his colleagues (Glenny *et al.* 1926) for improving the antigenicity of diphtheria toxoid, but has since been applied to other toxoids and to bacterial vaccines like those of *H. pertussis* (Chapter 74). Aluminium hydroxide is also effective (Hektoen and Welker 1933). Other successful adjuvants are lanoline in oil, cholesterol, salts of calcium and magnesium (Ramon *et al.* 1935); tapioca (Ramon 1937, 1939, Schmidt and Steenberg 1936); bacterial products like typhoid vaccine (Ramon 1936), staphylococcal toxin (Burky 1934, Swift and Schultz 1936); tubercle bacilli (Freund and McDermott 1942); serum containing heterophile antibodies (Kalinin *et al.* 1935). Both Glenny and Ramon attribute the action of alum and tapioca respectively to the stimulation of tissue lesions, from which the antigen is slowly liberated, thus providing a prolonged and continuous antigenic stimulus. We noted in the previous section that *H. pertussis* itself may have an adjuvant action. *Br. abortus* is also effective (Ramon *et al.* 1950).

The lesion produced by a single injection of alum-precipitated diphtheria toxoid is apparently the chief source of antigen for some time after its formation. Thus Blagowechensky (1938) excised the lesion made by alum-toxoid at varying intervals after its formation in the skin of guinea-pigs and found that, within a period of 10–20 days, the degree of immunity reached depended almost entirely on the length of time the lesion had remained in the body.

The adjuvant effect has also been attributed to the high absorptive capacity of the substances employed. Aluminium hydroxide, for example, will absorb proteins *in vitro* (Hektoen and Welker 1933, Cohen and Mosko 1943, Holford, Ludden and Stevens 1943). Faragó and Ujhelyi (1942) injected groups of guinea-pigs with diphtheria toxoid alone, with toxoid and $Al(OH)_3$ in the same injection sites, and with toxoid and $Al(OH)_3$ in different sites. The average antitoxin responses in unit per ml. after four weeks were 0.005, 0.4 and 0.02 respectively. In the last group the toxoid was apparently absorbed

phase of their virulence may be attributed in part to the formation of fibrinolysin.

Hyaluronidase (Spreading Factor, Invasin).³² It has been found in recent years that the permeability of the tissues is remarkably increased by a factor, often called the *Duran-Reynals factor* after its discoverer, present in certain mammalian tissues, notably the testes. Bacteria, vaccinia virus, and substances such as toxins, india ink and the like, diffuse rapidly from the site of inoculation when injected in conjunction with extracts containing this factor. Strains of staphylococci and streptococci that have no pronounced invasive powers may, in this way, be rendered highly invasive. This factor is also present in a number of bacteria notable for their invasive properties, such as certain strains of staphylococci and streptococci, pneumococci and certain of the obligate anaerobes such as the bacillus of gas gangrene. Among some of these organisms there is some degree of association between content of the Duran-Reynals factor and virulence; the non-invasive strains of staphylococci noted above contain little or none of this factor but become invasive when it is supplied, while the invasive strains produce the factor themselves. This substance has been found to be an enzyme, hyaluronidase, whose substrate is hyaluronic acid, a mucopolysaccharide consisting of acetyl glucosamine and glucuronic acid, which acts as a cement substance of the tissues and is found in synovial fluid and elsewhere in the body. The action of the enzyme in decreasing the viscosity of hyaluronic acid by hydrolysis is responsible for facilitating the penetration of the tissues by bacteria that produce it. The effect on the tissues is temporary in that, following inoculation of preparations of the enzyme, the dermal barrier is restored partially in twenty-four hours and completely in forty-eight hours.³³ It is of some interest that hyaluronic acid is also found in the capsular substance of some strains of streptococci. Such strains do not produce hyaluronidase and in its presence are denuded of capsules and more readily phagocytosed (see below). The ability of such strains to invade the tissues does not, of course, depend upon their elaboration of hyaluronidase. The activity appears to be antigenic, in that it is neutralized by antisera, but immunologically distinct from different sources; it has been suggested that the enzyme is combined with different proteins in different organisms.

Hyaluronidase is antagonized by an enzyme present in normal blood plasma which has been called anti-invasin I. An enzyme in bacteria, pro-invasin I, destroys anti-invasin I, and another enzyme in plasma, anti-invasin II, destroys pro-invasin I. It has been suggested that a balance between all these in the host-bacterial system determines whether or not invasion of the tissues will occur.³⁴

Capsules. The remarkable association between the presence of a capsule on a pathogenic bacterium and its virulence has been discussed elsewhere (Chapter 6). The capsular material, generally polysaccharide in nature al-

³⁴ Haas *Jour Biol. Chem.*, 1946, 163:63, 89, 101.

antigens were given without adjuvant. In the granulomata, the antigens were detectable in macrophages; and these were devoid of antibody.

It is generally believed that many adjuvants act by diminishing the rate at which antigen is released from the site of inoculation, or from cells which have taken it up. With Freund's adjuvant, Herdegen, Halbert and Mudd (1917) recorded the persistence of *Sh. flexneri* antigen at the injection site in mice for over 20 days, and Talmage and Dixon (1953) detected a large amount of serum globulin at a subcutaneous site 20-30 days after an inoculum which, given without adjuvant, largely disappeared within 5-10 days. The detoxifying action of many adjuvants is also consistent with the supposition of a slow release of a toxic antigen from a depot. Holt (1919, 1951) contends that AlPO_4 adjuvants promote the transport of toxoid antigens to the antibody-synthesizing cells; and that, because excision of the inoculation site in guinea-pigs after 14 days did not diminish the later antibody response, the fibrous reaction round the site, far from forming depots for slow release of antigen, must be sufficiently occlusive to prevent any release at all. Freund (1951) confirms this absence of a prolonged depot effect in rabbits given mixtures of his adjuvant and typhoid bacilli; excision of the injection site half an hour and eight days after injection decreased but did not eliminate the adjuvant effect, and excision after 14 days failed to modify it at all.

Slow release of antigen, or at least a more widespread and prolonged stimulus, might be expected to impose a secondary response on what starts as a predominantly primary stimulus (see Holt 1951). However, the merging of a primary and secondary response alone will not in all cases account for the action of an adjuvant. For example, when plain antigen is given intravenously to animals previously injected with adjuvant and antigen, a conspicuous rise in antibody titre occurs, indicating that the antigen slowly released after the first injection had not elicited all the secondary responsiveness of which the animals were capable (Freund and Bonanto 1942, Ward *et al.* 1950).

Mann and Welker (1949) record a curious adjuvant effect that can be induced in dogs by generally intoxicating the animals with egg white or ricin, injected by another route at the time of giving the antigen.

The Negative Phase.—Just as the injection of a considerable dose of a particular antigen into an animal that possesses a corresponding normal antibody may result in a temporary decrease in the concentration of that antibody in the circulating blood, the injection of a large dose of antigen into an animal that has already developed a certain concentration of antibody in response to earlier injections may be followed by a well-marked negative phase, which is usually followed in its turn by a rise in titre above the previous level. An illustrative example is afforded by the response of an immunized rabbit to two injections of horse serum, given intravenously at an interval of 5 days (Fig 262, p 1275). The importance of avoiding this negative phase in therapeutic immunization was emphasized by Wright and his co-workers (Wright 1909), though others maintain that in these circumstances there may be little diminution in the total immunity.

Stavitsky (1952) observed, in rabbits immunized with bovine globulin and given intravenous antigen, a diminution in the blood of specific antibody, granulocytes and complement, and a decrease in the capacity of the R.E. system to remove bacteria from the blood—results which suggest a temporary decrease in the antibacterial defences.

Schutze (1939) infected mice with a dose of *Salm. typhi-murium* sufficient to kill 50 per cent. of the animals in about 14 days. The injection of four substantial daily doses of a specific vaccine of proved efficacy, beginning on the second day of the disease, did not

though nitrogen and amino acids may be present, is not in itself toxic and cannot be regarded as analogous to toxins, hemolysins and similar substances. Rather the capsule appears to function as a defensive mechanism of the bacterium against the phagocytic activity of the leucocytes. Encapsulated bacteria may be ingested by a white blood cell but, instead of being killed and digested, remain within the phagocyte for a time and then may be extruded in a viable condition. The ability of an encapsulated bacterium to resist phagocytic destruction may, in fact, result in a wider distribution of the microorganism than it might otherwise attain, through transport within the phagocytic cell. It is of some interest in this connection that non-encapsulated, avirulent pneumococci are highly virulent for rabbits deprived of their leucocytes³⁵. It is perhaps suggestive that the polypeptide material making up the capsule of the anthrax bacillus contains d(—) glutamic acid³⁶ (p. 556). Since proteolytic enzymes attack only polypeptides built up from amino acids of the *L*-series, possibly an encapsulated anthrax bacillus would be highly resistant to the digestive enzymes of a phagocytic cell.

Whether the association of virulence and capsule formation may be entirely accounted for on the basis of bacterial defense against phagocytic destruction is not entirely certain, but such defense undoubtedly plays an important part. The presence of antibodies to the capsular substance breaks down this bacterial resistance, and immunization to the capsular material of the pneumococcus, for example, produces just as high a degree of immunity to pneumococcus infection as immunization to the entire bacterium.

Miscellaneous Factors. In addition to these more or less well defined and better known factors, a number of bacteria have been reported to produce substances which may be associated with virulence. Such, for example, are the necrotizing factor, or necrotoxin, produced by some staphylococci, which kills tissue cells, a hypothermic factor produced by Shiga dysentery bacilli, which lowers body temperature, an edema-producing substance formed by pneumococci, substances associated with the endotoxins of some of the enteric bacteria which affect the blood sugar levels of animals, and so on. Unfortunately, the discontinuous character of present information does not support any satisfactory generalization regarding bacterial virulence, but it seems clear that a pathogenic bacterium may have at its disposal a series of mechanisms, in combination peculiar to itself, which make possible a successful invasion of the tissues of the host.

In this connection it should be noted that bacterial virulence may be apparently enhanced by certain substances not of bacterial origin. The presence of silica in the lungs, for example, predisposes materially to pulmonary tuberculosis, the injection of calcium salts with tetanus bacilli aids, in some unknown manner, in the establishing of a nidus of infection. The suspension of bacteria, such as meningococci or typhoid bacilli, in solutions of gastric mucin markedly enhances their virulence, or, more precisely, interferes with the defense mechanisms of the host. It has been found that in the case of the

The Response of the Antibody-forming Apparatus to the Administration of Antigens otherwise than by Injection into the Tissues.

In defining the properties of an antigen on p. 223, it was stated that it should stimulate the formation of an antibody when introduced *parenterally*

FIG. 260.

Agglutinin production: response of a previously inoculated person to a single injection of typhoid vaccine.

Thus, the administration *per os* of killed suspensions of flagellated bacilli of the typhoid-paratyphoid group results in the production of somatic (O) agglutinins, but flagellar (H) agglutinins are either not produced at all, or only to low titre (Pijper and Dau 1930, Greenwood, Topley and Wilson 1931). The same difference between the formation of H and O agglutinins appears to hold in the case of the cholera vibrio (Pfeiffer and Lubinski 1930). Dysentery bacilli, when administered by the mouth, induced the formation of somatic agglutinins (Kanai 1921, Otten and Kirschner 1927) and of protective antibodies; though with *Sh. sonnei* in mice, a single dose of 10^8 bacilli intraperitoneally proved to be as effective in stimulating their formation as 15 daily doses of 10^9 bacilli by stomach tube (Cooper *et al* 1949). It is probable that analogous effects are produced by many other bacterial cells (see for instance Ross 1926, 1930, 1931, 1932, 1934, Downs and Bond 1937, Moor and Brown 1937, Torikata and Imaizumi 1938). The Vi antigen of the typhoid bacillus appears to be ineffective by the oral route Guarnacci (1939), for example, obtained low H and O titres in 68 per cent. of 227 persons given an oral vaccine of a (Vi + O) strain, but no Vi agglutinins.

In man, Greenberg and Fleming (1950) induced moderate antitoxin responses by oral diphtheria and tetanus toxoids, giving doses of 2,000 Lf or more of each antigen.

In all cases it would seem that administration *per os* is far less effective than inoculation into the tissues, in the sense that much larger doses have to be given and the antibody titre attained is usually lower; and that it has little practical value in medicine (Dolman 1948).

As regards other routes of entry, Stillman (1927, 1930) has shown that protective antibodies are produced in rabbits after the administration of living pneumococci by inhalation, but here we may be dealing with an active infection and consequent tissue invasion by living bacterial cells.

into the body. This caveat was included in the definition because administration *via* the intestinal tract does not ensure the passage of the antigen to the tissues in an unaltered and effective form. It may be broken down by the digestive enzymes. If it is not acted on by them it may never pass through the intestinal mucosa. Whether, in fact, any particular antigenic material administered by this route reaches the tissues in an unaltered form can only be determined by direct experiment. The available evidence suggests that some bacterial antigens, but not all, induce the formation of specific antibodies when administered by the mouth.

meningococcus the mucin interferes with the bactericidal action of the body fluids and, when mixed with peritoneal fluid, provides a medium for its growth.³⁷

Relative Pathogenicity of Bacteria. From the foregoing considerations it will be clear that the virulence of a bacterium is an expression of the efficacy of the aggregate of offensive mechanisms that it may possess. It is to be expected, then, that the bacteria constitute a continuous series of types ranging from those which are unable to infect higher organisms, such as the autotrophic forms, to those which produce a fulminating, widely disseminated and often fatal infection. The harmless saprophyte, *Bacillus subtilis*, for example, has been found to cause, on occasion, an eye infection in human beings (see also p. 565), and the saprophytic microorganism, *Bacterium prodigiosum* which is frequently used as a test organism in part because of its non-pathogenicity, has been found to produce disease following inhalation.³⁸ Somewhat more pathogenic is *Clostridium botulinum*, an organism which is also a saprophyte but which produces a highly potent soluble toxin. The bacterium is itself unable to infect the animal body; the toxin is formed outside the body and gives rise to disease only when ingested in a preformed state. *Clostridium tetani* is one step higher in the scale of pathogenicity; this microorganism resembles the botulinus bacillus in that it is essentially a saprophytic form that produces a soluble toxin. In this case, however, the bacterium is able to establish a nidus of infection in the tissues, albeit in a strictly localized area, and produce the toxin whose absorption gives rise to the symptoms of the disease. The diphtheria bacillus likewise generally produces only a local infection from which its toxin diffuses into the animal body but, unlike the tetanus bacillus, does not lead a saprophytic existence in nature but must maintain a close association with its host. The highly invasive bacteria, such as certain strains of streptococci and staphylococci, are, however, disseminated rapidly throughout the body, presumably because of their armament of fibrinolysins, spreading factor and the like.

A variety of types of infection may, therefore, be distinguished. A bacterium having but small ability to spread through the tissues produces a *localized or focal* infection. Such, for example, are the abscesses at the roots of the teeth, the infection of the heart valves in bacterial endocarditis, etc. A local infection is not necessarily of small consequence; not only may the local tissue destruction be highly significant to the host, as in pulmonary tuberculosis, but, when the microorganism produces a soluble toxin, a poisoning or *toxemia* results, as in diphtheria or tetanus.

Many pathogenic bacteria exhibit a tendency to localize in one tissue in preference to another, sometimes termed *elective localization*; the meningococcus, for example, most frequently localizes in the central nervous system, as do the so-called "neurotropic" viruses, and some of the streptococci show similar preferences for the joints. In some cases the tendency to localize is so marked that a pathogenic bacterium is infectious by one route but not by another, microorganisms such as streptococci, pneumococci, the tetanus bacillus and

or other cells. We have discussed in Chapter 7 the validity of the hypothesis that only proteins or protein-containing substances can induce an antibody response when injected into the tissues. It is clear that protein-free derivatives of fully antigenic substances not only act as haptens, but in some cases are themselves fully antigenic. There can be no doubt of the validity of Landsteiner's broad distinction between complete antigens and haptens, or of the association between decreasing chemical complexity, or molecular size, and a progressive loss of antigenic function; but it is not possible to predict at what stage in the degradation of a given antigen the complex will lose its full antigenic powers. In this connection it is instructive to consider the main type-specific antigen of the pneumococcus.

All the early studies on the purified polysaccharide components isolated from various bacteria, and in particular from pneumococci, suggested that these substances had the properties of haptens, and induced no immunizing or antibody-forming response when injected into the tissues. But subsequent observations have disproved this view.

Schiemann and Casper (1927) reported that the purified specific polysaccharide of the Type I pneumococcus, when injected into mice, produced an active immunity against living Type I pneumococci, but not against other types. They noted that this immunity was induced by the injection of small, but not of larger, doses. Schiemann (1929) recorded the immunization of mice by the injection of Type II pneumococcal polysaccharide, and noted that the blood of these immunized mice contained protective antibodies; though he was unable to demonstrate antibody production in rabbits. Francis and Tillett (1930) recorded observations suggesting that persons who were given repeated intradermal injections of the purified polysaccharide of Type I, II or III pneumococcus developed a specific local response which took the form of an immediate wheal and erythema; and that this response was associated with the appearance of specific antibodies in the blood. Similar observations have been reported by Finland and Sutliff (1932) and by Zozaya and Clark (1932). Zozaya and Clark (1933) recorded the immunization of mice with polysaccharide fractions from Types I, II and III pneumococci, and noted that small doses were more effective than larger ones; but their results were irregular except when the polysaccharides were adsorbed on collodion particles or on carbon.

Later studies by Avery and Goebel (1933) have thrown further light on this question. They were able to show that the Type I pneumococcal polysaccharide, as it occurs in the bacterial capsule, possesses acetyl groups. These groups are lost during the separation and purification of the polysaccharide by the methods which have been commonly employed. The acetylated form was found to induce active immunity in mice, when it was administered in small, but not in large doses. It did not induce antibody production in rabbits. Pneumococcal polysaccharides of various types were subsequently shown to be highly effective in inducing the formation of protective antibodies in man (Heidelberger *et al.* 1946, 1950). Analogous results have been recorded in animal experiments with substances from other bacteria. For example, in *Salm. typhi* and *Br. melitensis* the lipopolysaccharide O-substance is fully antigenic; whereas in *Sh. dysenteriae* the antigenicity of the O-substance is lost when the association between the polypeptide and lipopolysaccharide moieties of the molecule is destroyed (Chapter 8).

The Response of the Antibody-forming Apparatus to Active Infection.

The examples given above all refer to the response of the antibody-forming apparatus to the experimental injection of non-living antigenic substances. We may close this section with a few examples of its response to natural infections of the clinically obvious type. For simplicity we may confine our attention to acute infections, noting, however, that in the case of subacute and relapsing diseases,

others are relatively harmless when swallowed but regularly produce infection when injected into the tissues of a susceptible animal. Others, such as the organisms causing typhoid fever, cholera, the dysenteries and other enteric infections, are harmless when rubbed into the abraded skin but promptly produce disease when swallowed by man.

Bacteria present in a primary focal infection may spread by metastasis to set up multiple secondary foci, a condition known as *pyæmia*. Other bacteria may multiply in the blood stream, a condition known as *bacteræmia* or *septicæmia*, the invading bacteria may become widely disseminated through the capillaries of the tissues with the production of a fulminating, *generalized infection*.

Infection is, however, in part a function of the defensive mechanisms of the host, and in some cases a bacterium capable of further spread is held in check by these defenses and sets up a *latent infection* which may flare up when resistance is reduced. Such an inconclusive outcome may result in the *carrier state*, a condition in which a virulent bacterium, fully capable of producing disease, is harbored by a healthy and unaffected host. In this latter instance, however, the resistance of the host is not infrequently specific and a consequence of previous immunization.

Mixed and Secondary Infections. It has long been known that an individual might be attacked by two or more infective agents at one time. Diphtheria and scarlet fever, syphilis and gonorrhœa, pneumococcus pneumonia and typhoid fever, are combinations by no means unknown. It is possible that in some cases the different infections may originate nearly simultaneously, but such an occurrence is probably not common. Usually one infection precedes another, and the second is very frequently a more or less direct outcome of the first. Infection with certain microorganisms predisposes to secondary infection with the pneumococcus; acute tuberculosis may develop during an attack of measles, streptococcus invasion of the lung tissues is not uncommon in pulmonary tuberculosis. The secondary invader is commonly present in the host, but seems incapable of initiating an infection until the host defenses are weakened by the primary disease. Certain microorganisms that can cause primary infection are also frequently found as secondary invaders; pneumococci and streptococci are preeminent in this respect, and show a remarkable capacity for invading the body in the wake of other microorganisms.

Mixed infections of a somewhat different sort are those in which the principal pathogenic organism is accompanied by auxiliary bacteria, or, as some French bacteriologists have called them, *accomplices*, which by their presence influence the virulence of the chief infectious agent without themselves taking any very active part in the infectious process. Such cooperation is, of course, an instance of bacterial synergism which has been discussed previously. The aerobic bacilli which usually enter a wound along with tetanus bacilli probably facilitate the growth of the latter by providing anaerobic conditions. In other cases of mixed infections the invading bacteria may not influence one another directly but only indirectly in a joint breakdown of the defenses of the host; such is presumably the case in mixed infections of diphtheria bacilli and streptococci, and there is reason to believe that such a mixed infection is more severe than an infection with diphtheria bacilli alone—possibly spreading factor

formed by the streptococci increases the permeability of the tissues to the toxin formed by the diphtheria bacilli.

RESISTANCE

It is already apparent from the foregoing considerations of bacterial virulence that, although the ability of a microorganism to produce disease is conditioned by a series of mechanisms originating with the bacterium, pathogenicity must be evaluated in terms of the resistance of the host. As a rule, a pathogenic bacterium is limited to a small number of hosts; bacteria pathogenic for animals are not ordinarily pathogenic for plants; very few of the bacteria that can infect mammals are also pathogenic for cold-blooded animals; some are even restricted to the tissues of a single species. Resistance, like virulence, is made up of many factors, some of which are known either in more or less specific form or in the terms of generalities that serve as a cloak for ignorance; others are, in all probability, as yet unsuspected. Resistance to infection is, in a sense, somewhat more complex than virulence for, as will appear, not only are there specific barriers to infection variable with respect to species and even from one tissue to another in the body of a single animal, but the efficiency of these barriers is also a manifestation of general physiological well-being and hence they are subject to extrinsic or environmental influences.

The differentiation of resistance from natural immunity (p. 327) cannot be made with precision, for the two merge with one another and with acquired immunity without sharp lines of demarcation. In a general way they may be separated on the basis of specificity, resistance being non-specific with respect to the invading microorganism while immunity is sharply specific for a given parasite. The non-specific cellular response (p. 322) is intermediate between the two since the specific cellular immunity of the immunized animal is qualitatively the same, differing only in that it is markedly accentuated.

As in the case of virulence, the better known components of resistance are best considered one by one.

Species, Racial and Inherited Resistance. Species of higher organisms differ greatly from one another in their resistance to any given disease, a fact that has been suggested earlier in connection with the experimental reproduction of disease. In many cases resistance to infection is relative, for disease may sometimes be produced by the administration of massive doses of bacteria to a resistant animal, but in others it appears to be absolute. Man is, for example, apparently completely immune to cattle plague, and many of the lower animals are equally resistant to some diseases of man. In general the factors underlying differences in species resistance are unknown, but in a few cases body temperature or differences in anatomical structure have been found to account for the observed variation. Pasteur's classic experiment in which he rendered the naturally resistant hen susceptible to anthrax by chilling it in cold water, and the converse of this experiment, the production of anthrax in the resistant frog by raising its body temperature to 25° to 35° C., may be explained in terms of unfavorable body temperatures. Similarly, cold-blooded animals are not susceptible to human tuberculosis and warm-blooded animals are not infected by the tubercle bacilli of cold-blooded animals. The insuscep-

Another procedure that has been stated to supply a non-specific stimulus to the antibody-forming apparatus is the injection of various metallic salts, colloidal solutions or other substances. We may ignore, from our present point of view, those instances in which the effect of such injections is limited to an increase in the bactericidal power of the blood. Such effects will be more conveniently considered in Chapter 52.

Walbum and his collaborators (Walbum and Mørch 1923, Walbum and Berthelsen 1925, Walbum 1925, 1926, Schmidt 1926, Ørskov and Schmidt 1928) have recorded numerous experiments along these lines. They conclude that the injection of salts of certain metals, especially those of cobalt, manganese and beryllium, causes an increase in the production of antitoxin, or of agglutinins, if given early in the course of immunization, and leads to a secondary rise in titre if injected when the antibody titre has commenced to fall. Several investigators have, however, failed to confirm these observations (McIntosh and Kingsbury 1924, Horgan 1925), and the protocols included in some of Walbum's reports suggest that the response is very irregular.

Steabben (1925) used agar, gelatin, a silver sol and an iron sol, and found that the injection of these colloids had no power to increase the antibody titre when this had become steady, though when injected at the same time as the bacterial antigen they might increase the antibody response. This last effect is clearly analogous to the adjuvant action of certain substances we have already discussed.

Obermayer and Pick (1904) recorded that animals immunized 3 months previously showed a fresh formation of precipitin after the injection of a 5-10 per cent. solution of peptone. Fleckseder (1916) stated that the injection into human beings of deuterio-albumose or nucleic acid gave rise to a secondary rise in antibody titre. Also Weichardt 1922 and Wahl 1935 have recorded a secondary rise in antibody titre. Both review the evidence on protein substances as non-specific stimuli; in most cases the stimulus is irregular, and the antibody response is small compared with that to a specific antigenic stimulus.

We may next consider those cases in which the non-specific stimulus is provided by a complex antigen, similar in type to that providing the initial specific stimulus but possessing no known common antigenic factor. So far as this antigenic dissimilarity is in fact complete the case does not differ in its essentials from those we have considered above.

Dreyer and Walker (1909) recorded a secondary rise in agglutinins for *Bact. coli* after the intraperitoneal injection of killed staphylococci into previously immunized rabbits. Conradi and Bieling (1916) state that rabbits immunized against *Salm. typhi* show a secondary rise in agglutinins after various non-specific stimuli, such as those provided by the injection of *Bact. coli*, dysentery bacilli and *C. parvulus*. They also injected rabbits with typhoid, paratyphoid and dysentery specific stimulus and another as the secondary non-specific stimulus, and noted many instances of a secondary rise in agglutinins. His protocols, however, indicate clearly that, where the secondary response was well marked, there was some antigenic relationship between the two kinds of bacteria employed.

Rosher (1924) was unable to detect non-specific stimulation of antibody production in tests with the following pairs of dissimilar antigens, the first given as a primary antigenic stimulus, the second as a non-specific stimulus: *Bact. coli* and *Staph. aureus*; *Bact. coli* and sheep red cells; *Salm. paratyphi A* and a suspension of mixed unrelated bacteria; *Salm. typhi* and *Salm. paratyphi B*, *Salm. enteritidis* and living tubercle bacilli. The second injection acted only as a primary stimulus by the antigen used, and did not affect the titre of specific antibodies for the previously injected antigen.

tibility of experimental animals such as guinea pigs and rabbits to the enterotoxin produced by some bacteria is possibly attributable to their lack of a vomiting mechanism. As indicated earlier, resistance to a given infectious agent is not necessarily associated with phylogenetic relationships, and there is no pattern from which the resistance or susceptibility of an animal can be predicted by logical processes; the tabulation of animals susceptible to a given disease represents information acquired largely by trial and error.

Domestic and Experimental Animals. Not only do species of higher organisms differ in their resistance to infectious disease but the races comprising a susceptible species likewise appear to differ among themselves. There are many instances of differences in resistance to infectious disease in varieties or strains of animals. The relative resistance of Algerian sheep to anthrax is well known and inbred Berkshire swine have been found to be highly resistant to brucellosis.³⁹ That this is a true racial immunity which is, as might be expected, inheritable, has been demonstrated by extensive experimental investigations with laboratory animals. The earlier studies of Wright and Lewis⁴⁰ showed that marked differences in susceptibility to tuberculosis existed between inbred families of guinea pigs, differences which were transmitted to the offspring. Later work, summarized by Webster,⁴¹ Hill⁴² and Greenwood *et al.*,⁴³ has been confined, for the most part, to studies on the susceptibility of mice to infection with *Salmonella typhi-murum* and similar bacteria, it has been shown that resistance to such infections may be raised or lowered by selective breeding, sometimes to a remarkable degree. Similarly, strains of mice differ in their susceptibility to murine typhus, and Lurie⁴⁴ has bred strains of rabbits resistant and susceptible to infection with tubercle bacilli. It is of interest that resistance to bacterial endotoxin may also be raised or lowered by selective breeding. Resistance does not behave as a simple Mendelian character but is to some extent specific in that a race having increased resistance to infection with one microorganism is not necessarily unusually resistant to another. For example, in Webster's work mice selected for resistance to infection with *Salmonella enteritidis* showed increased resistance to pneumococcus and Friedlander's bacillus infection, but were more susceptible to the virus of louping ill than the strain selected for susceptibility.

Considerable interest has attached to the mechanisms underlying inherited resistance and susceptibility, and in recent years suggestive results have been reported by a number of workers. Thus, in Lurie's⁴⁴ studies resistance was associated with low skin permeability as assayed by intradermal inoculation of india ink, increased rate and intensity of antibody (agglutinin) response, and the development of a high degree of hypersensitivity (see also p. 343). Gowen and Calhoun⁴⁵ have shown that in mice there is a marked correlation

between numbers of leucocytes and resistance to mouse typhoid. Similarly, Severins, Roberts and Card⁴⁶ have found that resistance and susceptibility of breeds of chickens to *Salmonella pullorum* infection is associated with numbers of lymphocytes, and Oakberg⁴⁷ has observed differences in liver and spleen in resistant strains of mice associated with the ability of macrophages to digest phagocytosed bacteria. Differences in susceptibility may, of course, be a reflection of corresponding differences in immunizability, i.e., ability to respond to antigenic stimuli with antibody production. Scheibel,⁴⁸ for instance, has been able to divide strains of guinea pigs into good and poor producers of diphtheria antitoxin on immunization.

Races of Man. The relative resistance of races of man to infection has been the subject of considerable interest and such investigation as has been possible. Under ordinary circumstances in this country the non-white races are much more susceptible to infectious disease than the white race. There are, however, certain exceptions. Thus, the influenza epidemic of 1918 appears to have had a greater impact upon the death rate for white youths than upon that for the non-white population in the same age group. Similar exception may be noted in the case of Baltimore Negroes who showed a lower ratio of clinical diphtheria to immunizing infections than corresponding white children.⁴⁹ It is quite generally recognized, too, that the Negro has a remarkable degree of resistance to erysipelas, and the more favorable response of the Negro to all forms of treatment for gonorrhoea is well known.

Special interest has attached to the white and non-white tuberculosis death rates, both crude and age-specific (p. 643). Whether the observed high mortality in the non-white represents a racial susceptibility or is entirely a reflection of economic status has been the subject of considerable discussion. Studies on this question made in the Army (p. 644) would seem to indicate a true racial difference.

There also appear to be differences between the less well-defined "races" of man. There is evidence that the Irish are less resistant to tuberculosis than certain other elements of the American population, such as the Italians.⁵⁰ On the other hand, the Jewish race is considered by many to be relatively resistant to tuberculosis; in spite of a high incidence of infection, the mortality is very low.⁵¹ To what degree the evidence supports the hypothesis that races⁵² of man differ in their susceptibility to this and other diseases, such as pneumonia, is problematical, for adequate control of the environmental factors is difficult if not impossible. However this may be, twin studies on tuberculosis indicate the operation of genetic factors in the resistance of man to this disease,⁵³ and

⁵¹ For example, see Drolet: Amer. Rev. Tuberc., 1924, 10:280.

⁵² In a number of these studies racial stocks were determined for first generation immigrants on the basis of parental birth place.

⁵³ Cf. Kallman and Reisner: Amer. Rev. Tuberc., 1943, 47:549.

from that of an intravenous injection. After an intramuscular injection an anti-serum usually reaches the blood stream more slowly than after an intraperitoneal injection but more rapidly than after a subcutaneous injection; though Christensen (1952) found substantially equal rates of absorption in man and rabbits given tetanus antitoxin by the subcutaneous and intramuscular routes. The rate of absorption from subcutaneous and intramuscular injection sites is increased when the antibody is given together with hyaluronidase (McClellan and Morgan 1933, Boquet *et al.* 1952).

Another point of some importance in connection with passive immunization is illustrated in Figs. 268 and 269 (Glenny and Hopkins 1922).

FIG. 268.

Disappearance of antitoxin from blood of three normal rabbits, after intravenous injection of antitoxic horse serum.

(After Glenny and Hopkins.)

FIG. 269.

Disappearance of antitoxin from blood of three rabbits, previously sensitized to normal horse serum, after intravenous injection of antitoxic horse serum.

(After Glenny and Hopkins.)

In Fig. 268 is recorded the rate of disappearance of antitoxin from the circulation of 3 normal rabbits after the intravenous injection of 0.5 ml. of diphtheria antitoxin, derived from the horse. Fig. 269 gives a similar record in the case of 3 rabbits that had received previous inoculations of horse serum. These were "immune" or "sensitized" to horse serum—the relation of the immune to the sensitized state is discussed in Chapter 51—and in consequence eliminated the antibody from their circulation much more rapidly than did the normal rabbits. The same phenomenon will occur when a person who has previously received an injection of horse serum is given an antitoxic or antibacterial serum derived from that animal (see Hooker and Follensby 1931).

the question is rather one of the occurrence of practically significant genetic segregation.

A given disease, however, may be relatively mild in its effect on races of man which have been in contact with it over a long period of time, but assume a highly virulent form in other races to which it is new. Measles, for example, a mild disease to civilized man, has been a scourge to certain primitive races. In other cases, diseases originally highly virulent have become apparently less so with the passage of time, leprosy is not as widespread as it was in biblical times, and syphilis is a considerably milder disease today than it was in the sixteenth century. Phenomena such as these have been taken by some to indicate the development of a racial immunity through a selection of more resistant individuals, and by others to suggest an adaptation of the microorganism accompanied by a loss of virulence. At the present time, it is not possible to differentiate sharply between these two, possibly both effects are operative.

It should be pointed out in this connection that what might be called a pseudo-racial immunity may be manifested by a race in close association with a given infective agent. Many individuals have the disease, the survivors are immune, and this immunity is passively transferred to the offspring (see p. 333), who are infected before this passive immunity entirely disappears and consequently have the disease in a mild form but become solidly immune. The immunity is passively transferred to the third generation, and the process continues *ad infinitum* as long as the race is in contact with the disease. Some such racial immunity of the adults arises as a result

Age. The effect of the age of an animal on its resistance to infections disease is variable, being clearly apparent in some instances and indistinguishable in others. In many cases there is a direct relation between age and resistance, the young being more susceptible than the older individuals. The suitability of the developing chick embryo as a menstruum for the cultivation of certain filterable viruses to which the chicken is apparently completely insusceptible, and the results of the experiments of Woolpert and his colleagues⁵⁴ on the infection of the guinea pig fetus, may be regarded as examples of an exaggerated susceptibility of the immature organism. The marked susceptibility of the guinea pig fetus to tuberculosis drops off after birth, and young, mature and old animals have been found to be progressively more resistant to this infection. Similar results have been observed with other infections such as equine encephalomyelitis in mice, St. Louis encephalitis in mice, and in the resistance of the rat to diphtheria bacilli and diphtheria toxin.

It is well known that the very young child does not respond well to active immunization, Sauer,⁵⁵ for example, has reported poor results in active immunization against whooping cough, and antidiphtheria immunization of the newborn is not successful. This inadequate immune response is undoubt-

⁵⁴ Cf. Woolpert: Amer. Jour. Path., 1936, 12:141, Woolpert et al.: Jour. Exp. Med., 1938, 68:313, Gallagher and Woolpert: Jour. Exp. Med., 1940, 72:99, Dettweiler, Hudson and Woolpert: Jour. Exp. Med., 1940, 72:623.

⁵⁵ Sauer: Amer. Jour. Path., 1941, 17:719.

structure of antigens and antibodies, was put forward independently by Breinl and Haurowitz (1930), Alexander (1931) and Mudd (1932). Ignoring minor differences in the views of its sponsors, this hypothesis assumes that all antibodies are globulins newly synthesized under the directing influence of the antigen. This influence is exerted through a union, physical or chemical, between the peptides of the nascent globulins and the active groupings of the antigen, during the globulin synthesis. The globulin thus formed is dissociated from the antigen after a certain stage has been reached, and the latter is thus able to leave its stereochemical imprint on successive molecules of antibody globulin synthesized under the same conditions.

We have seen that certain cells of the lymphoid-macrophage system appear to be the site of antibody formation, but the circumstantial evidence does not implicate the cells of that system in which antigen is first deposited (p. 1254). If, however, we can take such cells as a model of the antibody-forming cells—and it is not impossible that some of them are transformed into antibody-forming cells—the localization of antigen—or at any rate of radioactive markers attached to antigens—first in the microsomes and then in the mitochondria of the macrophages of the liver and spleen (Crampton and Haurowitz 1952, Fields and Libby 1952) suggests that synthesis takes place in granules of the cell cytoplasm.

The reaction of antigen, or of an effective derivative of antigen, with the synthetic sites, appears to take place fairly rapidly. The results of transplanting splenic tissue, at varying intervals after exposure to antigen, into a normal animal indicate that the antigen loses its capacity to stimulate cells in the recipient animal within a day or so (p. 1259); and experiments on the time-relations of radiation-sensitivity of antibody formation (p. 1256) suggest that the modification of the synthetic site by antigen is initiated within a few hours. In this connection we may also note that the antigenicity of bacillary bodies is partly destroyed soon after their ingestion by macrophages (Walsh and Smith 1951). But although the antigen, as a substance that will stimulate a response in a second animal, may disappear before antibody synthesis has ceased, it does not follow that it disappears as a determinant of antibody formation (Topley 1930). Moreover, it should be noted that transposed antibody-forming tissue loses its capacity to produce antibody in a few days or weeks. There is other evidence, in short-term tests at least, that antibody formation lasts as long as antigen is present in the body. Thus there is a direct relation between decline of antibody formation and disappearance of antigen in rabbits making a primary response to tobacco mosaic virus (Libby and Madison 1947, Erickson *et al.* 1953).

Pauling (1940) who reviewed the physico-chemical basis of the hypothesis, considers that the difference between normal and antibody globulin lies not in the ordering of the amino-acid residues of the polypeptide chains, but in the manner of the folding of their otherwise similar constituent polypeptide chains, to form polypeptide laminae and ultimately the globular protein. According to Pauling, the ends of the folds, which when packed together will constitute one of the surfaces of the completed molecule, are capable of taking up many configurations, whose variety and stability are determined by the presence of an excess of proline and hydroxyproline residues at the point of folding. When an antigenic substance with a well-defined configuration of active groups is present in the cell, it influences the configuration at the ends of the folded polypeptide chains, thereby inducing the formation of an antibody receptor. Pauling suggested that, if globulin mole-

edly at least partially responsible for infection of the very young with bacteria ordinarily regarded as harmless saprophytes. Cass,⁵⁶ for example, has reported epidemic infection of the newborn (in a maternity ward) with *Bacterium aerogenes* which took a septicemic form, and the *Bacterium coli* infection of foals known as scours is well known.⁵⁷ Complement deficiency in the newborn and less active phagocytosis by Kupffer cells are possibly associated with this failure to respond to antigenic stimuli and bacterial invasion.

The rise in resistance coincident with the development of an animal to maturity has been interpreted by some workers as indicative of a "maturation immunity" in which the ability to withstand infection is associated with the

Fig. 29. The age incidence of certain infectious diseases. Note the predominance of the diseases of childhood in the early years, the increase in tuberculosis in the young adult years and the marked increase in lobar pneumonia with advancing age. Scarlet fever rate multiplied by a factor of 40, and diphtheria rate by a factor of 10 for comparative purposes. Data for 1940 from the reports of the Bureau of the Census.

ductless gland secretions. Experimental studies in which precocity has been induced by the injection of androgens have, however, been disappointing, and maturation immunity must be regarded as a hypothesis which is suggested by certain clinical results but for which there is no sound experimental proof.

The well-known increased susceptibility of the aged to certain of the infectious diseases is reflected not only in the incidence but also in the mortality of infections such as pneumonia. The quantitative (exponential) relation between the probability of death from a given disease and age was observed many years ago (1825) and is known as Gompertz's law. The physiological alterations underlying senile debility and mortality are probably in the nature of an accumulation of degenerative changes.⁵⁸

antigenic units must pass to one of the daughter cells at each division. Burnet and Fenner prefer the assumption of an antibody-forming capacity, independent of the continued presence of antigen, which is transmitted to descendant cells by some hereditary process. (It has been objected that such a process should lead to the hereditary transmission of the capacity to the offspring; but there is no necessary connection between the two, for it is highly unlikely that the immune response in the adult would have any genetic effect on the segregated reproductive cells in the gonads.)

They postulate that the serum globulins are products of self-reproducing, intracellular, globulin proteinases, and represent a stage in synthesis when the molecule has the essential structure of the enzyme, but is without enzymic activity. At this stage it may be turned out into the circulation as a globulin. In the cell, however, the synthesis proceeds to completion, and more proteinase is formed, its normal function being to hydrolyse substances of endogenous origin. In the presence of antigen, the configuration of the proteinase is modified so as to hydrolyse the antigenic matter, and, when the antigen is gone, the proteinase reproduces itself in the modified form, both in the original cell and its descendants. According to Burnet, the continuously accelerated output of antibody observed during the secondary response is characteristic of an autocatalytic process such as he postulates, not the production of antibody from a fixed number of antigenic templates; and he attributes the change in reactivity of antibody observed with prolonged immunization (see Chapter 7) to the profounder modification of the globulin proteinases by the products of a more complete intracellular hydrolysis of the antigen.

That the secondary response is sometimes exponential in part of its course does not necessarily point to any one kind of process, biological or other—a fire in a wood-pile grows exponentially. The exponential increase may, for example, reflect an increase in the antibody-forming cells, thus giving an opportunity to unemployed templates in regions where antigen has accumulated; for, as Haurowitz (1952) points out, even a small dose of intravenous antigen is equivalent to several thousand molecules per liver cell.

The specific immunological paralysis, induced in adult mice by massive doses of pneumococcal polysaccharide (p 1262), and the analogous phenomenon of specific acquired tolerance induced in animals treated with the antigen during their foetal life, are not readily explicable in terms of either hypothesis. But both appear to be associated with persistence of antigen. In the first, persisting polysaccharide was demonstrable, and in the second, the antigens were foreign tissue cells that are either known, or may reasonably be presumed, to persist in the animal receiving them.

We are not in a position to decide between these hypotheses. Both depend upon arguments by analogy with other biological processes, and it is not in all cases clear how relevant these analogies are. It is clearly impossible to prove in all cases that antigen is persisting as such. Heidelberger (1952) indeed suggests that both mechanisms may be operative; and that antigens, like the bacterial polysaccharides, which are not readily metabolized in the body act mainly as continued stimuli, whereas the readily hydrolysed protein antigens, like diphtheria toxoid, induce a heritable change in the synthetic powers of the antibody-forming cell.

Sevag (1951, 1954) developed another concept, based largely upon a study of the immunology of enzymes and their corresponding antibodies, of antigens as specific catalysts of antibody formation. This, it may be noted, is in direct contrast to the views of Burnet and Fenner, who regard antigens as modifiers of the intracellular proteinases.

In practice, the relation of age to resistance to infection is complicated by many factors. The human baby, for example, is relatively resistant to a number of infections for the first six months of life as a result of passive transfer of antibodies from the mother either via the placental circulation *in utero* or by means of colostrum after birth. Similarly, the increased resistance to a disease such as diphtheria which appears with physical development arises primarily as a result of inapparent infection rather than maturity alone. (The so-called natural antibodies are discussed on p. 329.)

Sex. A number of diseases exhibit a difference in sex incidence, pneumonia and epidemic meningitis, for example, are more common in males than females, while scarlet fever, typhoid fever and others occur somewhat more frequently in females. Except for a few years in the forty-one-year period 1900-1940, the female death rate for white youths has been consistently lower than that for males, though the reverse has been true for the non-white population in this country. In the decade 1931-1940 the gap between the female and male in the non-white population was closed and in 1940 the female and male death rates for non-white youths were exactly the same at 5.0 per 1000. Corresponding rates for the white population were 1.4 for females and 2.0 for males. In the case of tuberculosis, variability in the age-specific mortality rates indicates a differential response on the part of the sexes (p. 644). A sex differential is also indicated by the aftermath of the 1918 influenza epidemic, which appears to have had a more unfavorable effect upon female mortality than that of males in the 15 to 24 age group, as indicated by the relatively high female death rate for all racial groups for several years after the epidemic.

It has been suggested that this difference between the sexes might result from resistance having some of the attributes of a sex-linked character, or, since differences in sex incidence are most pronounced during and after puberty, something in the nature of maturation immunity may be involved. There is no sound evidence to support the first of these hypotheses. Regarding the second a certain amount of experimental evidence has been reported, the most precise relating to skin permeability, which has been found to be greater in female rabbits than in males.⁵⁹ It has also been shown by Bennison and Coatney⁶⁰ that female chicks are significantly more susceptible to infection with the chicken malaria parasite, *Plasmodium gallinaceum*, than are males, treatment with male and female sex hormones did not affect the differences between the two. Any explanation of the observed sex differences must, of course, take into consideration other factors such as occupation, risk of exposure and the like.

Climate and Season. That both climate and the season of the year exert marked effects on the incidence and mortality of a number of infectious diseases is well known. In tropical climates, for example, the acute upper respiratory infections are not so common as in the temperate climates, but the dysenteries are more common in the tropics than in the temperate zones. The seasonal incidence of the infectious diseases is also common knowledge.

the decline in titre of circulating antibodies after a maximum has been reached is usually delayed. An immunized differs from a normal animal, not only in the possession of a particular antibody, but in its capacity to produce that antibody rapidly and in large amount in response to the specific stimulus. In certain circumstances the preoccupation of the antibody-synthesizing cells with the secondary response may diminish their response to a primary inoculation of another antigen made at the same time.

(6) Repeated inoculations are more effective in raising the antibody titre to a high level than a single injection, even of a very large dose. Just as there appears to be a limit to the titre that can be attained by increasing the size of a single dose of antigenic material, so there is a limit beyond which repeated injections fail to raise the titre.

(7) The injection of a large dose of antigen into an animal in whose blood the corresponding antibody is present frequently results in a temporary fall in the concentration of that antibody, followed in most cases by a secondary rise. The efficacy of the dose of antigen in stimulating this secondary rise may be diminished by the combination of antigen with the circulating antibody—a “blanketing” effect apparently due to a consequent accelerated breakdown of antigen in the tissues.

(8) Antibody formation may be induced by the administration of antigens by the mouth, by inhalation, or by intranasal instillation. Administration by these routes is, in general, less effective than direct inoculation into the tissues. In the case of administration *per os* there is evidence that antibodies may be produced against certain antigenic components but not against others.

(9) Although the majority of naturally occurring antigens are proteins, or contain protein components, other substances, such as complex polysaccharides, are capable of inducing an active immunity, and of stimulating antibody production.

(10) The antibody-producing apparatus may in certain conditions be stimulated by non-specific substances. Two effects may be distinguished:

(a) An adjuvant action of substances injected into the tissues simultaneously with antigen, or during the period of increasing antibody response. The action of adjuvants is complex. In some cases, they appear to act by inducing tissue lesions from which the release of antigen is slowed and prolonged; in others, by promoting reactions that lead to a more efficient transport of antigen to the antibody-forming cells. A stimulus to the multiplication of antibody-forming cells cannot be excluded from the effect of certain adjuvants.

(b) A stimulation of the antibody-forming apparatus that results in some increase in the concentration of a normal antibody or in the renewed production or mobilization of an antibody previously produced in response to a specific stimulus—the anamnestic reaction. The evidence for such stimulation is conflicting; this non-specific response often occurs very irregularly, is usually trivial or transitory in its effect, and is never as great as the response to a further injection of the specific antigen. In some cases it may be mediated by hormones of the adrenal cortex.

(11) The rate at which injected antibody reaches the blood and tissue fluids of a normal animal and the concentration there attained depend in great part on the route by which the antiserum is injected. After an initial period of dilution in the blood and body fluids, passive circulation at a rate similar to that

meningococcus meningitis occurs predominantly in the winter and spring, poliomyelitis in the late summer and early fall, and so on. One of the most striking relationships of season to incidence of disease is that of Asiatic cholera; the epidemic season coincides with hot weather and shows a remarkable correlation with precipitation and relative humidity.

In a great many instances the influence of climate and season upon the incidence of disease may be attributed to opportunities for transmission of the causative organism, such as crowding in poorly ventilated rooms, seasonal or geographic occurrence of an insect vector and so on, but in others the factors responsible for seasonal incidence are unknown.

In recent years specific evidence has begun to accumulate which substantiates the opinion that resistance varies with season, temperature and similar factors. For example, the intensity of the brain reaction of mice inoculated with *St. Louis encephalitis virus* and that of guinea pigs inoculated with endemic typhus virus have been found to have been the greatest in summer and the least in the winter over a period of years; mice adapted to existence in a moist heat have been found only one quarter as resistant to infection with hemolytic streptococci as those adapted to a cool environment; the morbidity and mortality rates in murine typhus infection in mice are affected by environmental temperature; and the resistance of mice to pneumococcus infection is similarly affected. It is not improbable that future investigation will yield systematic knowledge of the effect of climatic factors on susceptibility to disease.⁶¹

General Physiological Well-Being. Whatever resistance to disease an organism may possess by virtue of species, race and the like is profoundly influenced by its general physiological state. In general, resistance is at its height when the organism is functioning normally in every respect, and is reduced by a variety of factors which interfere with and alter the normal physiological state. In some cases previous infection may reduce resistance to such a point that infection with the less virulent bacteria may take place, as in the secondary infections; in others, functional disorders such as diabetes mellitus bring about a reduction in resistance to infection. More common, however, are the deleterious effects of inadequate diet and fatigue.

Nutrition. The relation between susceptibility to infection and faulty nutrition has been of considerable interest since the discovery of the vitamins and consequent study of the deficiency diseases, in some of which, such as xerophthalmia, infection plays a part. Attention has been directed particularly toward vitamins A (carotene) and C (ascorbic acid), and there is no doubt that a deficiency of the first of these substances results in a marked lowering of resistance. The reduced resistance appears to be associated with a reduced humoral immune response, but this is in part at least compensated for by an accentuated phagocytic response to infection. Diets qualitatively and quantitatively inadequate, not only with respect to other vitamins but in other ways also, may likewise predispose to bacterial infection.⁶² Recently Cannon⁶³ has

emphasized the importance of adequate protein intake, and he and his co-workers have shown that depletion of the protein reserves of experimental animals by maintenance on low protein diets interferes markedly with antibody formation, *i.e.*, the synthesis of immune globulin. While antibody formation is significantly interfered with by moderate protein depletion, a severe depletion also interferes with the normal functioning of the cellular defense mechanisms as evidenced by reduced phagocytosis.⁶⁴

Other than this, just how malnutrition brings about a reduction in resistance is not known, present information indicates that the effect is a general one. It is of some interest that this unfavorable effect is not limited to the undernourished individual but may be transmitted to offspring. Experimental studies have shown,⁶⁵ for example, that the diet of mice, genetically homogeneous in resistance to an infection, affects the resistance of offspring to a greater degree than the diet of the offspring themselves. In this connection, statistical studies⁶⁶ have suggested that the mortality rates of adult human life are in part a function of nutritive and other elements of the environment of childhood, in other words, the effect may be a delayed one, but the evidence on this point is not altogether indubitable.⁶⁷

The marked reductions in resistance associated with inadequate diets are in no sense specific; resistance to infection in general is reduced, and there is no relation between lack of a single dietary factor and susceptibility to a particular infection. A number of attempts have been made to demonstrate such a relation, ascorbic acid, for instance, has some small capacity to neutralize diphtheria toxin, but vitamin C deficiency does not predispose to infection with the diphtheria bacillus any more than with other organisms, such as the tubercle bacillus.

Since inadequate diet, and vitamin A deficiency in particular, reduces resistance to infection, it has been supposed that resistance might be raised in hypervitaminosis. Experimental evidence, however, does not support this supposition, the normal level of resistance maintained by the organism on an adequate diet cannot be appreciably raised by the administration of vitamin A in quantities in excess of that normally required.

The apparently contradictory observation that resistance to infection with a number of the viruses is increased by inadequate diet has been made by a number of workers.⁶⁸ That it is not completely inconsistent with the lowered resistance associated with protein depletion and other dietary deficiencies is indicated by the consideration that the viruses are obligate intracellular parasites; possibly a healthy cell is of primary importance to multiplication of the virus and the depleted cell is an unfavorable medium for development, thus masking so to speak the lessened immune response associated with nutritional deficiencies.

Fatigue. It has long been known to the clinician that bodily rest is a valuable adjunct to the treatment of disease, and there is clinical evidence

which suggests that resistance to the initial infection may be reduced by excessive fatigue. Experimental evidence on this point is scanty and to some degree conflicting, but it is probable that the unfavorable effect of fatigue on normal physiological well-being is reflected to some extent in an increase in susceptibility to infection. The normal white rat, for example, is highly resistant to anthrax, but when exhausted by work in a treadmill becomes susceptible,⁶⁹ latent *Salmonella enteritidis* infections in the same experimental animal may be activated by fatigue to such a degree that the outcome is fatal.⁷⁰ Similarly, studies on human beings have indicated that an individual may be rendered transiently susceptible to the common cold by fatigue.⁷¹

Other mechanisms operative in the resistance associated with general physiological well-being are obscure. Studies on resistance to the common cold in population groups made by subjecting the incidence data to an analysis of variance among groups have strongly suggested that an as yet undefined constitutional factor is operative in the etiology of the clinical infection.⁷² The studies of Locke⁷³ have indicated that the capacity to maintain effective circulation and the ability to withstand the effects of sudden temperature changes are associated with resistance to experimental infection. The adverse effects of sudden changes in temperature and humidity on the organism, reflected in changes in the nasal mucosa, are, perhaps, a manifestation of temperature shock. Attempts to associate such shock, vitamin deficiencies, fatigue and other elements of the non-specific resistance of health with specific defense mechanisms such as the capacity to form antibodies, have not been uniformly successful.

The External Defenses of the Organism. The cellular organization of the animal body is a closed system with respect to the outside environment from which it is separated by the skin, mucous membranes and intestinal mucosa. These structures, generally impermeable to particulate material of the size of bacteria, constitute the first line of defense against invading microorganisms and one that is, for the most part, highly effective. While mechanical obstruction contributes in no small part to the efficacy of these barriers, both skin and mucous membranes also play an active part in the protection of the organism against bacterial invasion, as will appear.

The Skin. As a rule, the unbroken skin presents a more or less impassable barrier to microorganisms. Bacteria are found normally on the skin between the superficial horny cells, but ordinarily are not able to penetrate deep into the tissues unless favored by some cutaneous injury, such as a wound or burn. The ducts of the sweat glands and the hair follicles are, however, vulnerable points, and experiment has shown that it is possible for bacteria to penetrate the skin through these channels.

The skin, however, is not an inert surface upon which bacteria may survive, but is, as experimental work of the last few years has shown, actively bactericidal. Arnold and his co-workers⁷⁴ found that bacteria which do not

occur normally on the skin, such as *Bacterium prodigiosum*, the typhoid, colon and enteritidis bacilli, and hemolytic streptococci, are rapidly (in some cases within ten minutes) destroyed when swabbed on the clean skin of the palm of the hand. Possibly related is the fungistatic action of the free saturated aliphatic acids in the hair fat of adults.⁷⁵ The autosterilizing capacity of the skin is markedly reduced by dirt and is apparently a property of live skin, the skin of a cadaver dead only fifteen minutes showed little or no bactericidal activity. Bacteria normally present upon the skin, such as the white staphylococci, are not appreciably reduced in numbers when swabbed on the clean skin, a fact which probably accounts for their constant presence on the body.

The Conjunctivae. Bacteria and dust particles settling in the eyes are removed relatively rapidly by the mechanical flushing effect of the tears. The lacrimal secretions contain a substance, *lysozyme*, which is also present in certain tissue extracts and in egg white, which destroys some species of saprophytic bacteria. Fleming⁷⁶ who discovered lysozyme, described one species of bacteria, *Micrococcus lysodeikticus*, which is particularly susceptible to the action of this lytic substance, as high a dilution as 1:40,000 of tears has brought about complete lysis of these microorganisms. Lysozyme has been found to be identical with the avidin of egg white and has been isolated in crystalline form.⁷⁷ None of the pathogenic forms, however, appears to be unusually susceptible to the action of lysozyme, and it probably plays no important part in the protection of the organism against invasion.

The Nose, Nasopharynx and Respiratory Tract. Bacteria and other particulate material present in inspired air are rapidly removed by passage through the tortuous nasal passages lined with mucous membrane to whose moist surface they cling. In this way air is largely freed from bacteria in the upper respiratory passages, those that pass the larynx are caught in the bronchi and few reach the ultimate ramifications of the bronchioles. The process is so efficient that expired air contains almost no bacteria except those that are expelled in droplets by sneezing, coughing and talking.

The moist film which covers the mucosa of the upper respiratory tract and in which bacteria removed from inspired air and those arriving via the lacrimal secretions are embedded consists of mucus, a thin, highly viscid substance that, in a sense, constitutes a continuous web or membrane overlying the surfaces within the nose, sinuses, pharynx and esophagus. This film of mucus is in constant motion as a result of the activity of cilia which sweep the mucus and its bacterial content toward the oropharynx, where it is swallowed. The exchange of mucus is rapid, that covering the posterior two thirds of the nose is replaced every ten or fifteen minutes, while that over the anterior third is removed every hour or two.⁷⁸ Although mucus itself has no bactericidal activity, when combined with ciliary activity it constitutes a remarkably efficient means of ridding the upper respiratory passages of bacteria. Davies,⁷⁹ for instance, has shown that all particles above 7 μ in diameter

an interval of 10 days elapsed after the sensitizing dose before hypersensitiveness was established; and that no hypersensitiveness resulted when large injections of serum were given at short intervals.

The same phenomenon was studied independently by Rosenau and Anderson (1906, 1907), who established the strict specificity of the reaction. They found that guinea-pigs sensitized to horse serum showed little if any hypersensitiveness to the serum of other animals, such as the rabbit, cat, dog, pig, sheep, chicken or man. Similarly, guinea-pigs sensitized to horse serum did not respond in any abnormal way to the subsequent injection of egg white, vegetable protein or milk. They noted also that the amount of serum required to produce sensitization was extremely small; as little as 0.000,001 ml. sometimes induced typical hypersensitiveness. The amount required to produce anaphylactic shock in a sensitized animal was, however, considerably greater (0.01-0.1 ml.). They confirmed the existence of a latent period of the anaphylactic reaction, extending over an indefinite period, extending over several months at least.

These observations have been repeatedly and consistently confirmed by later workers. Animals may be actively sensitized by the injection of any substance that is antigenic in the full sense. The sensitizing injection may be given by any route. Often a single sensitizing dose suffices. In some animals, and with some antigens, it is necessary to give more than one sensitizing injection, and to use doses far larger than the minute amount that suffices in the particular case of the sensitization of the guinea-pig to horse serum; but as a rule the injections must not be too large, nor too often repeated. Large doses, however, must be used for animals, like the mouse, that are refractory to sensitization. The dose needed may also vary with age; for the one-year-old guinea-pig it is reported to be twenty times that for animals up to 22 weeks old (Coulson and Stevens 1949).

Sensitization is also possible by the oral route (Winter 1944) or by the inhalation of antigen in the form of an aerosol (Kallos and Pagel 1937).

As regards the shock-inducing, or "shocking" injection, either the antigen used for sensitization, or certain types of separated haptens containing the specific reactive grouping, are effective in eliciting the characteristic symptoms. The route of injection is important. Intravenous inoculation gives the most constant results; in some animals it is the only effective route for this purpose. In the guinea-pig, which is peculiarly susceptible in this respect, shock may be produced by intraperitoneal inoculation, but larger doses are required. Within certain limits the size of the shocking dose, nevertheless, appears to be a secondary factor in determining the severity of shock. In dogs, for example, Dragstedt (1943b) found that shock did not become more fatal with increase in size of the shocking dose; the fatality was primarily determined by the degree to which the animal had reacted to the sensitizing dose. The generalization, based on older observations, that the shocking dose must be considerably larger than the minimal sensitizing dose, is not justified. A shocking dose of 0.5 μ g ovalbumin is reported as sufficient in guinea-pigs sensitized with 1 μ g. of the antigen (Coulson *et al.* 1949).

A curious and significant fact emerged early in the widespread investigation which followed the opening-up of this new field of research. The symptoms and lesions of anaphylactic shock were found to be constant for a given animal species, irrespective of the nature of the sensitizing antigen; whereas these symptoms and lesions differed sharply from one animal species to another. Thus the guinea-pig reacts in the same way when anaphylactic shock is produced with horse serum,

which are inhaled are retained in the upper respiratory passages of the rabbit, about half the particles $3\ \mu$ in diameter are similarly removed, and the remainder plus practically all those $1.5\ \mu$ in diameter and smaller penetrate into the lungs. Substantially the same results have been reported by Boyland, Gaddum and McDonald⁸⁰ with other experimental animals and man. The bacteria that penetrate the upper respiratory passages and lodge in the bronchi and bronchioles are probably phagocytosed by the fixed aveolar epithelial cells and the wandering leucocytes that enter the bronchioles and sacs, a process discussed at greater length elsewhere.

Lysozyme is, of course, present in the nasal mucus and it has been observed⁸¹ that the normal serous secretion of the nose contains a virus inactivating agent (VIA) distinct from lysozyme. The activity is virucidal for the influenza and certain other viruses inactivated by sodium desoxycholate but what part it plays in resistance to infection is not clear.

The Mouth, Stomach and Intestinal Tract. The healthy mouth ordinarily contains great numbers of bacteria, but, except in the case of those organisms which have established themselves, this flora is a transient one, the microorganisms being constantly removed through a flushing action of saliva and as constantly supplemented by fresh contamination. Saliva is but mildly bactericidal,⁸² and the removal of bacteria is practically entirely a mechanical process. The microorganisms flushed to the back of the mouth meet with those from the nose and, with them, are swallowed.

Bacteria reaching the stomach are subject to the strongly acid environment of the normal gastric juice, and there is no doubt that the great majority of them are destroyed there. Some do, however, reach the intestinal tract, perhaps because they are embedded in solid particles of food and thus protected or because they are able to withstand a short exposure to the bactericidal action of the gastric secretions. Generally, very few viable bacteria are found in the stomach, but the numbers of microorganisms increase in the small intestine with the rise in pH from the duodenum to the ileum. The large intestine contains great numbers of bacteria derived not only from the upper levels of the intestinal tract but also from the multiplication of bacteria present in the intestines as normal inhabitants. As in the respiratory passages, mucus plays an important part in the mechanical removal of bacteria. Here, however, the mucus does not form a uniform coating over the intestinal mucosa but is present as a meshwork. The villi free themselves from particles by movements which bring them in contact with the mucus to which the particles, including bacteria, adhere. The mucus, with the embedded microorganisms, is rolled up into small masses and moved outward by the peristaltic movements of the bowel.⁸³ Bacteria, then, which enter the mouth and upper respiratory tract are eventually extruded with the feces.

The Genital Tract. The normal genital tract is remarkably free from bacteria. The urethra in both male and female is normally sterile, a consequence,

acute heart failure. His observations and conclusions have been confirmed by other workers (Drinker and Bronfenbrenner 1924, Grove 1932a, b).

Anaphylactic Shock in the Dog.—A sensitized dog, after receiving an intravenous injection of the specific antigen, shows marked signs of restlessness and excitement. Within a few minutes the animal vomits and usually passes urine and faeces, the latter sometimes blood-stained. It then collapses and lies prone. The muscles of the limbs are relaxed, and the dog appears extremely weak. Respiration is slow, and often deep and laboured. Stridor may be heard, and a little froth may exude from the lips. In rapidly fatal shock the weakness progresses, renewed diarrhoea and vomiting set in, and coma, occasionally associated with epileptiform convulsions, leads on to death. It has been pointed out by Dean and Webb (1924) that the reaction almost always occurs in two stages, the initial acute symptoms being followed by some signs of recovery. In fatal cases these soon give place to the second stage of increasing collapse. In other instances severe initial shock is followed by a rapid return to normal.

As demonstrated by Biedl and Kraus (1909), anaphylactic shock in the dog is associated with a progressive fall in blood pressure; later investigations (Pearce and Eisenbrey 1910, Dale 1920b) have made it clear that this is not due to any failure of output from the heart or to any influence of the central nervous system, but to the collection and stagnation of the blood somewhere in the tissues. The studies of Dale and his colleagues (Dale 1920b) indicate that capillary dilatation is the essential factor.

Manwaring (1910) performed a large number of experiments in an attempt to localize the site of reaction; and, having found that shock did not occur when the abdominal vessels were ligated, proceeded to explore the rôle of the various abdominal viscera by a series of operative experiments designed to exclude each in turn. He found that the exclusion of the liver inhibited acute shock in dogs; and his observations were amply confirmed by subsequent workers (Voegtlin and Bernheim 1911, Denecke 1914). These results accord well with the findings at necropsy. The congestion of the abdominal viscera has been noted by many observers; and Weil (1917) points out that in dogs dying of anaphylactic shock in its acutest form the single outstanding feature at necropsy is the enormous distension and congestion of the liver.

We may briefly note certain additional phenomena, which seem to be general to anaphylactic shock as displayed by any of the species so far investigated, though not developed to an equal degree in all of them. There is commonly a sharp decrease in the circulating leucocytes and platelets; and this, as Webb (1924) has shown, is associated with an aggregation of polymorphonuclear cells in the capillaries of the lungs, a phenomenon clearly analogous to that which follows the intravenous injection of bacteria in immunized animals. In rabbits, the arterioles of the ear are conspicuously contracted during shock; circulating leucocytes adhere to the capillary walls and in some cases form leucocytic emboli (Abell and Schenk 1938). Removal of circulating leucocytes and their retention in the tissues was also demonstrated by Dragstedt, Ramirez de Arellano and Lawton (1940) in the isolated lung of sensitized rabbits, when perfused with blood containing the specific antigen. The blood platelets share in the aggregation of leucocytes in the vessels of the lungs and other tissues. There is a decrease in the coagulability of the blood of the dog, but not of the blood of rabbits or guinea-pigs (see Adams 1953). The work of a number of investigators (see Dragstedt 1941) has excluded changes in the blood elements concerned in normal coagulation as the cause of this phenomenon, which appears to be due to the liberation of heparin during shock (Jaques and Waters 1940). There is a decrease in the amount of complement in the circulating blood (see Ecker 1939, Stavitsky *et al.* 1949); and there is a fall in the body temperature.

Anaphylactic Shock in the Mouse.—Mice are relatively resistant to shock. Refractoriness varies with the breed of animal, and in some cases depends on insusceptibility to sensitization, not insusceptibility to shock (Weiser *et al.* 1941). Large doses of antigen are required for sensitization, and for the intravenous shocking dose (Solotorovsky and Winsten 1953). Freund's adjuvant greatly improves the sensitizing power of proteia

perhaps, of the flushing action of the slightly acid urine. The few bacteria that may be present are confined to the region of the meatus. The normal vaginal secretion is acid and is markedly bactericidal toward most species of bacteria.

Normal Flora. A microorganism somewhat better able to resist the defensive mechanisms of the host but at the same time unable, except when resistance is reduced to a low level, to invade the body tissues, may exist in conjunction with the host as a part of the latter's "normal flora." The staphylococci which are able to resist the bactericidal action of the skin are almost invariably present on these surfaces and are regarded as "normal" inhabitants. The scanty bacterial flora of the vagina, on the other hand, is composed almost entirely of aciduric bacteria; and the bacterial types present in the intestines are determined to a considerable extent by the type of food material present, *i.e.*, the diet of the host, and by the pH of the various intestinal levels. The composition of the intestinal flora is also affected to an indeterminate extent by antagonistic relationships among the bacteria present and potentially present. It has been shown,⁸⁴ for example, that some strains of coliform bacteria elaborate an antibiotic, colicin, which is effective against dysentery bacilli. Certain kinds of bacteria, such as lactobacilli, spirochetes, various cocci and the like, exist in the mouth in the interstices between the teeth and in and under tooth plaques and constitute a normal flora characteristic of this region. The bacteria commonly present in the nose and throat consist of still different forms, such as pneumococci, Friedlander's bacillus, green and hemolytic streptococci, etc. These organisms, while in a sense a normal flora, are not so well established as the flora of some other regions, and the nature of the microorganisms present may be determined in large part by the kind of bacteria which are constantly entering the upper respiratory tract.

As long as the resistance of the host is maintained at a sufficiently high level, the bacteria constituting the normal flora do no harm. If, however, resistance is reduced in some manner, the more virulent forms may invade the tissues and set up an infection. The congestion of the nasal mucosa, and the consequent interference with ciliary activity and the movement of mucus, which follows the temperature shock of chilling, not infrequently make possible infection by bacteria such as hemolytic streptococci or pneumococci, which are already present.

⁸⁴Frederick and Levine: Jour. Bact., 1947, 54:785, Halbert. Jour. Immunol., 1948, 58:153.

animal that has received an injection of the serum of an actively sensitized animal will respond to the subsequent injection of the corresponding antigen by developing acute anaphylactic shock. Passive sensitization may be effected with equal or even greater certainty by an injection of the serum of an animal that has been "immunized" against a given antigen by repeated injections, so that it is not itself sensitive to the antigen in question. In either case the injection of the serum is not usually followed by the *immediate* sensitization of the recipient. An interval of some hours must elapse between the injection of the sensitizing serum and the injection of the corresponding antigen if typical shock is to be regularly obtained. For maximal sensitization the interval may be even longer—4 to 6 days (Kellaway and Cowell 1922). The incubation period is in part a function of the dose of antibody. In passive sensitization of guinea-pigs to a constant dose of ovalbumin, Benacerraf and Kabat (1949) induced fatal shock immediately after the antibody, but only when a dose of 2 mgm antibody nitrogen was used; whereas the injection of 0.06 mgm. antibody nitrogen sufficed for shock after a lapse of 5 hours.

No incubation period appears to be necessary for passive intravenous sensitization in the dog (Sherwood *et al.* 1948).

Under suitable experimental conditions, an analogous reaction, "reversed passive anaphylaxis," may be induced in the guinea-pig by injecting antigen first and antibody later (see Kellett 1935). Both in "reversed" and direct anaphylaxis, shock is produced when the two intravenous injections follow one another immediately (Dean *et al.* 1936, Zinsser and Enders 1936, van den Ende 1939). Van den Ende, testing serum proteins as antigens, obtained reversed passive anaphylaxis with globulin but not albumin—suggesting that the reaction is determined by the fixation of globulins—either as antigen or as globulin antibody.

The efficacy of an antiserum in the induction of passive anaphylaxis appears to be related to its content in specific antibody measured as precipitin (Doerr and Russ 1909). The amount of specifically precipitable antibody nitrogen required for passive sensitization of guinea-pigs to fatal shock was estimated by Kabat and Landow (1942) and Kabat and Boldt (1944) to be about 0.03 mgm.; that is, less than 0.2 mgm antibody globulin. Similar figures were obtained with both rabbit and guinea-pig antibody (Benacerraf and Kabat 1949). With this minimal sensitizing dose, the optimal shocking dose of ovalbumin was about 50 times the amount serologically equivalent (Chapter 7) to the antibody injected. It should be noted that non-precipitating antibody is also effective in passive sensitization (Kabat and Benacerraf 1949). This type of antibody, discovered first as a co-precipitating antibody (p. 235), must not be confused with the non-precipitating, skin-sensitizing antibody discussed on p. 1321, which does not necessarily confer anaphylactic hypersensitivity. There seems no reason for supposing that the reagents concerned differ from those with which our other immunological studies have made us familiar. The experimental study of this phenomenon has, however, brought to light a relationship that is probably of fundamental importance in immunological mechanisms. Different antisera, produced by the immunization, or sensitization, of animals of different species against a single antigen, differ widely in their ability to induce passive sensitization in a given species of animal.

Thus, Avery and Tillett (1929) and Brown (1934b) found that guinea-pigs could be sensitized to pneumococcal polysaccharides by the injection of antipneumococcal sera prepared in the rabbit, but not by antipneumococcal sera prepared in the horse. Again (see Friedberger and Hartoch 1909, Scott 1931, Hartley 1940), guinea-pigs cannot be

Chapter 9

THE TRANSMISSION OF INFECTION

Whatever the pathogenic powers of a bacterium and the efficiency of the defensive mechanisms of the host, an essential preliminary to the production of infectious disease is a meeting of the parasite and its prospective host. In some instances in which the bacterium is naturally saprophytic, it enters the body by accident, so to speak; such, for example, appears to be the case in tetanus, gas gangrene and similar infections. In most instances, however, the bacteria that produce disease are more or less closely adapted to a parasitic existence, and pass from one animal body to another with only a relatively brief sojourn in the external world. In general, then, the transmission of infection is a process in which the causative microorganism is transferred, either directly or indirectly, from a diseased to a healthy susceptible animal.

The elucidation of the mechanisms involved in this transfer is a matter of considerable practical as well as theoretical importance. If the sequence of events that precedes infection is known, it may be, and often is, possible to interrupt it at its most vulnerable point and thereby control the spread of disease. From the theoretical point of view, disease is by no means entirely a matter of host resistance and microbic virulence; it is, in a very real sense, the outcome of the interaction of the host and parasite populations. It is at this point that the study of the infectious diseases transcends the bacteriology of clinical medicine with its emphasis on the individual case, and assumes broad biological significance as a problem in interspecies competition.

The equilibrium that tends to become established between the host and parasite populations is an unstable one in that the factors which determine it—i.e., the character of the host population in particular and possibly that of the parasite population, as well as the environmental factors which affect their relationship—are constantly shifting, and the equilibrium ever has a tendency to establish itself at a new level. The shift may be a sudden and violent one whose outward manifestation is an explosive outbreak of disease or, less commonly, may take the form of a gradual increase or decrease in the incidence of the disease.

The factors associated with the maintenance or shift of this equilibrium are the subject matter of *epidemiology*.¹ The term epidemiology is best regarded in this broad sense and therefore includes the study of the transmission of endemic disease, i.e., disease which has a low incidence but is con-

¹ For a general discussion of the principles and methods of epidemiology see Frost: *Collected Papers*, pp. 493-542. Commonwealth Fund, New York. 1941. A brief discussion of theoretical epidemiology is given by Aycock and Russell. *Amer. Jour. Med. Sci.*, 1943, 206-399.

or galactoside did not induce shock when injected into sensitized animals, but each inhibited anaphylactic shock when injected immediately prior to the injection of the corresponding carbohydrate-protein compound. Klopstock and Selter (1929) carried out similar experiments and obtained similar results, using compounds of protein with atoxyl, or with the sodium salt of metanilic acid. Landsteiner and Levine (1930) sensitized guinea-pigs to the D- and L-isomers of *p*-amino-tartranilic acid, in each case coupled to horse globulin. The subsequent injection of the corresponding active groupings coupled to chicken globulin induced anaphylactic shock. The shock could be specifically inhibited by a preliminary injection of a compound of resorcinol with the active grouping concerned. Similar results were obtained with guinea-pigs passively sensitized to *p*-amino-arsanilic acid, the active substance being coupled to tyrosine for the inhibition tests. In later experiments Landsteiner and van der Scheer (1932, 1933, 1938) were able to induce shock by injection of the azo-dye compounds alone into animals sensitized with the appropriate azo-dye-proteins.

Specific Desensitization.—The specific desensitization of sensitized animals was recorded by many of the earlier investigators (Otto 1905, Rosenau and Anderson 1906, 1907, 1908, Besredka and Steinhardt 1907, Gay and Southard 1908). Desensitization—as then observed, and in the sense in which this term is now commonly employed—differs from the inhibitory effect induced by simple haptens in that the desensitizing agent is the complete antigen, which is capable, when administered intravenously in adequate doses, of inducing typical shock. The desensitizing effect is obtained, in place of acute shock, if a very minute dose of antigen is given and repeated, or if rather larger doses are given by a route, such as the subcutaneous, which ensures slow absorption. The essential conditions for success appear to be the administration of an amount of antigen that is adequate in total by some method that prevents any rapid accumulation in the circulating blood. It must be emphasized that desensitization, however it is induced, is purely temporary, the anaphylactic, or hypersensitive state being re-established in a few days or weeks (Vallery-Radot *et al.* 1936, Adelsberger 1936, Gernez 1936). There is no good evidence of a permanent removal of an allergic state by specific desensitization.

The Mechanism of Anaphylactic Shock.

It is clear that acute anaphylactic shock, as induced by any of the procedures that have been described above, belongs to the category of the specific antigen-antibody reactions. The only question at issue is the mechanism by which this primary reaction gives rise to the series of events that characterize acute shock in any given animal species.

There are two opposing views. According to one the reaction between antigen and antibody, occurring in the circulating blood or in the tissue fluids, leads to the production of a toxic substance, anaphylatoxin, which, acting on susceptible cells, gives rise to the characteristic syndrome. According to the other the primary reaction occurs not in the blood or tissue fluids but on or in the tissue cells; and the reactions that characterize acute shock are due not to any toxicity of the antigen-antibody compound itself, or of any derivative from it, but to cellular disturbances initiated by the antigen-antibody reaction. As we shall see, the picture that has been pieced together during the last twenty years or so derives, in all its essential outlines, from the cellular school, though it contains details reminiscent of the anaphylatoxin hypothesis.

The Humoral or Anaphylatoxin Hypothesis.—The chief protagonist of this conception of the mechanism of acute anaphylactic shock was Friedberger (1910, 1912,

stantly present in a population, as well as the study of *epidemic* disease, i.e., disease of high morbidity which is only irregularly present in clinically recognizable form. In this connection it may be noted that the term *pandemic* is often applied to an epidemic of unusually great proportions. These categories, although useful, are not mutually exclusive; a disease endemic in a community may, at times, attain the proportions of an epidemic and later subside to an endemic level.

Essential to knowledge of the epidemiology of disease are certain characteristics of the etiologic agent and of the clinical infection which determine the possible channels of transmission. The more important of these are.

- (1) the route by which the infective agent enters the body,
- (2) the route by which the infective agent leaves the body,
- (3) the resistance of the microorganism to the deleterious effects of the outside environment;
- (4) presence or absence of an intermediate host; and
- (5) the relation between frank, clinically recognizable disease and the discharge of virulent bacteria from the body.

The Carrier. With regard to the last, additional explanation is desirable. In the early days of bacteriology it was assumed that the contact of host and parasite could have only one or the other of two outcomes; either no infection occurred, owing presumably to high resistance on the part of the host, or clinically characteristic disease developed in the individual. More recently it has become clear that an intermediate state, the establishing of a symptomless infection, may occur. Such infections are, of course, inapparent and concealed and may be demonstrated only by isolation and identification of the infectious agent. An individual so infected is termed a carrier.

Two types of carriers are commonly differentiated, the casual carrier who harbors the microorganism temporarily, a matter of a few days or weeks, and the chronic carrier who remains infected for a relatively long time, sometimes throughout life. Such individuals serve, of course, to disseminate the infectious agent. In the first group are the great majority of carriers of the diphtheria bacillus, meningococcus, pneumococcus, certain streptococci, etc., and the second includes carriers of certain of the enteric bacilli, especially the typhoid bacillus. A third type of carrier is often differentiated, the convalescent carrier who remains infected for a greater or lesser length of time after recovery from the disease. These last do not, of course, fall into the category of concealed infections. Sharp separation is sometimes not possible, however, for the casual or chronic carrier may, in fact, be convalescent from the disease in a form either atypical or so mild as to go unrecognized (ambulatory cases).

While it is now commonplace to recognize the existence of the carrier state, the implications of the general principle that infection may occur without disease are frequently neglected. Thus it follows that clinically apparent infections may constitute only a part, in some instances only a very small part, of the infections continually taking place. Clearly, then, if an important proportion of the infections are of the concealed type, a reasonably accurate estimate of the extent to which the infection is disseminated in the host population cannot be arrived at on the basis of cases of the disease. The implications

anaphylactic reactions in the guinea-pig—is in general a prominent feature, though it may vary in degree. There is, however, a high frequency, with these anaphylactoid reagents, of capillary thromboses and embolism in the lungs.

Among such anaphylactoid reagents—and this has been a source of error in several experiments supposed to support the humoral view—must be included all antisera that contain a high concentration of Forssman antibody (see Doerr and Pick 1913, Taniguchi 1922, Scott 1931; see also Neter 1947). The toxic effect is here due, in part at least, to a direct action of the heterophile antibody on the corresponding antigen contained in the guinea-pig's tissues, and may be regarded as a peculiar example of reversed passive anaphylaxis. When the serum is injected by the ordinary intravenous route the first stress of this reaction falls on the endothelium of the lung capillaries, resulting in lesions which appear to be identical with those produced by the scrotoxins.

Another anaphylactoid reagent is ordinary peptone (de Waele 1907, Biedl and Kraus 1909, Hirschfelder 1910, Doerr 1914, 1922, Dale 1920a, 1929, Manwaring, Clark and Chilcote 1923). The resemblance of peptone shock to true anaphylactic shock is very striking. In the guinea-pig there is the typical contraction of the bronchioles, in the dog the fall in blood pressure and the congestion of the liver. In both there may be found the loss of coagulability of the blood and the multiple small subserous hæmorrhages that are characteristic features of acute anaphylaxis in general. In dogs peptone shock is apparently accompanied by a release into the blood of heparin and histamine (Quick 1936, Holmes *et al.* 1941, Rocha e Silva *et al.* 1947); and peptone activates proteases in the serum (Burdon *et al.* 1951, Ungar *et al.* 1953). Peptone and other anaphylactoid agents cause aggregation of leucocytes in the blood vessels of the lung and other organs, as occurs also in anaphylactic shock. After peptone shock, as after non-fatal anaphylactic shock, dogs remain in a refractory state, but peptone refractoriness depends on the degree of shock suffered, and cannot be induced by sub-shocking doses of peptone (Dragstedt 1913a).

Histamine Shock.—Histamine is an amine derived by decarboxylation from histidine. The toxic syndrome produced by histamine reproduces very faithfully several of the characteristic features of acute anaphylaxis. In the guinea-pig the spasm of the bronchioles is constantly present in its most typical form. In the dog (Maunter and Pick 1915, Dale 1929) the muscular walls of the efferent hepatic veins are very sensitive to histamine; in response to traces of this substance they constrict and dam back the blood in the capillary spaces of the liver. But there are also quite definite points of difference. The distension of the dog's liver with blood and lymph in anaphylaxis is far more severe and persistent than that produced by histamine. Nor does the blood become incoagulable in histamine poisoning; but this we should expect if the incoagulability was due to the liberation of heparin.

When powerful histamine-liberating drugs (see Feldberg and Miles 1952) are injected intravenously into guinea-pigs, the resulting release of histamine from depots of bound histamine in the body produces an acute anaphylactoid shock.

The importance of these observations lies in the fact that histamine is a relatively simple substance of known chemical constitution, the pharmacological action of which has been studied in considerable detail. It can hardly be a mere coincidence that on intravenous injection it mimics so closely the syndrome produced by the injection of a non-toxic antigen into a sensitized animal.

Summarizing the evidence up to this point, we recognize a number of substances, ranging in complexity from histamine and synthetic histamine-liberators to enzymic proteins, which can induce a shock mimicking anaphylactic shock. With some of these, the shock is produced by the liberation of histamine; with others, it is associated with the activation of serum proteases. We shall defer the discussion

of this are several. For example, diseases which occur sporadically and do not seem to be easily or often transmitted from the sick to the well, such as poliomyelitis, meningococcus meningitis, lethargic encephalitis, pneumococcus pneumonia, etc., may be as widely disseminated and readily communicable as measles or the common cold, but the clinically distinctive disease is the exception rather than the rule. Furthermore, the rise or decline of infectious disease or its age or geographical distribution may not reflect a corresponding variability in the prevalence of the infection but may, rather, be a consequence of variation in the case-carrier ratios. Though here inferred from the observed occurrence of the carrier state, none of these possibilities remains purely hypothetical for all have been found to exist. Thus, carriers of virulent pneumococci do not occur predominantly in the higher age groups, nor diphtheria bacillus carriers in the school child, where the morbidity of these diseases is highest; diphtheria bacillus carriers are as common in the tropics as in temperate climates despite the relative rarity of clinical diphtheria in the hot climates, and so on. In many other cases, such as that of poliomyelitis, such a situation is suspected but technically difficult to prove. It will be obvious, therefore, that the recognition of the carrier state and its implications is basic to sound epidemiological thinking and of primary importance to the understanding of the mechanism of spread of the infectious diseases.

The epidemiological factors given above are most readily and most satisfactorily determined by experimental study when a disease is of known etiology, but sometimes may be approximated to a relatively satisfactory degree by indirect evidence. For example, although the famous Broad Street Pump epidemic occurred prior to the discovery of the etiology of cholera, the indirect evidence plainly indicated to Snow that the infective agent left the body in the feces and entered the gastro-intestinal tract via the contaminated well water.²

Epidemiological Types of Infectious Disease. On the basis of such fundamental information, the infectious diseases may be separated into a number of epidemiological types which, despite certain limitations, serve to illustrate the diversity of ways in which infection may be disseminated.³ A rough classification, based on the assumption that the human being is the recipient of infection and that the control of diseases of man is the point at issue, follows:

- (1) diseases of lower animals transmissible directly to man (rabies, tularemia, glanders, etc.);
- (2) diseases of animals or man transmitted by insect vectors in which
 - (a) the insect acts as a mechanical carrier (the house fly and typhoid fever),
 - (b) the parasite multiplies in the insect vector (bubonic plague),
 - (c) the parasite is transmitted from one insect generation to the next by egg infection (spotted fever), and
 - (d) the parasite undergoes a portion of its life cycle in the insect (malaria);
- (3) diseases of animals or man transmitted indirectly
 - (a) by water (the enteric infections such as typhoid fever, cholera, etc.),
 - (b) by milk (scarlet fever, bovine tuberculosis, undulant fever, etc.).

³ Epidemiological types of infectious disease are discussed briefly by Baker: *Amer. Jour. Trop. Med.*, 1943, 23 559.

be rendered hypersensitive by prolonged perfusion with diluted serum from anaphylactic or immunized guinea-pigs. This hypersensitiveness is hardly perceptible after 1 hour's perfusion, but it is easily perceptible after 5 hours' perfusion, a period strikingly similar to the latent period in passive sensitization in the living animal. Nevertheless, an almost immediate sensitization of the isolated uterus can be produced *in vitro*, resembling in speed that which must precede the anaphylaxis following the almost simultaneous injection of antigen and antibody into the whole animal.

A fact of great significance was established by Dale while investigating the response of the uteri from immunized guinea-pigs. These animals had received repeated injections of horse serum increasing in amount. Some of them were injected intraperitoneally with 5 ml. of horse serum but showed no sign of shock. Nevertheless, the uterine horns, removed from other animals of the same series, reacted with a typical contraction on the addition of horse serum to the bath, thus showing that fixed antibody is present in the immune as well as in the hypersensitive animal, and lending strong support to the view that the immune guinea-pig is protected by the excess of antibody in its circulating blood.

The protective function of circulating antibody is clearly illustrated in some of Weil's experiments (see Fig. 270). A series of guinea-pigs were passively sensitized by the intraperitoneal injection of 0.1 ml. of rabbit-v-horse serum, i.e. the serum from a rabbit immunized by repeated injections of horse serum. Three days later one animal received 2 ml. of this antiserum (20 sensitizing doses) and immediately thereafter 0.01 ml. of horse serum (1-2 anaphylactic doses). This guinea-pig showed slight symptoms only. It was killed; its uterus was tested by Dale's technique, and its serum was injected into another normal guinea-pig which was tested 24 hours later by the injection of horse serum. The uterus of the first animal gave a typical reaction, showing that it had anchored the antibody injected 3 days previously, and that this fixed antibody had not combined to any appreciable extent with the 0.01 ml. of antigen subsequently injected under cover of a protective dose of antibody. The second guinea-pig developed typical shock, showing that a considerable amount of the antibody injected into the first guinea-pig immediately prior to the injection of the antigen had remained unneutralized in the circulation. Another sensitized guinea-pig of the same series received 2.5 ml. of the rabbit-v-horse serum (25 sensitizing doses) and immediately thereafter 0.4 ml. of horse serum (52 anaphylactic doses). It died in acute shock, showing that the amount of antibody present was not sufficient to protect the cells containing the fixed antibody from this excessive dose of antigen. The uterus, removed immediately after death, was injected

serum. It developed moderate symptoms only, showing that the greater part of the circulating antibody in the animal that died of acute shock had been neutralized by the large dose of antigen. It should be noted, however, that serum antibody does not always protect. Morris (1936a) recorded that an excess of antibody injected into sensitized guinea-pigs led to an increase, not a decrease, of sensitivity.

Using antigens labelled with radioactive iodine as shocking agents, Dixon and Warren (1950) observed an apparently specific uptake of antigen by the lung of the anaphylactic guinea-pig.

Taking the evidence as a whole, the different behaviour of the hypersensitive and the "immune" guinea-pig may with some confidence be attributed to a difference in the relative concentration of fixed and circulating antibody.

If, however, we turn to other animals the evidence is more confused (see Dale 1920b, Scott 1931); and the observations of Manwaring and his colleagues (1923-28) on acute anaphylaxis in the dog are particularly difficult to fit into the relatively simple picture that we have drawn above. It seems, however, altogether unlikely that the mechanism of acute anaphylaxis differs fundamentally from one animal to another; and it is probable

- (c) by food (typhoid and paratyphoid fevers), and
- (d) by inanimate objects or fomites, such as books, towels, etc. (scarlet fever, diphtheria and the like),
- (4) diseases of man transmitted directly
 - (a) by infective droplets—air-borne infection (the respiratory diseases and others) and
 - (b) by direct contact (the respiratory and venereal diseases in particular).

Air-Borne Infection. Of these modes of transmission air-borne infection is one of the most important. In recent years Wells⁴ and his associates have shed new light on the mechanism of transmission of disease, especially respiratory disease, from man to man by the experimental elucidation of droplet infection. It was postulated many years ago by Pflügge that such diseases could be transmitted by infective droplets. The droplets which he studied, however, were greater than 0.1 mm. in diameter and fell to the ground soon after expulsion by sneezing or coughing, seeding the air for only negligible distances. Epidemiological considerations, however, seemed to demand air-borne infection effective at considerable distances. Wells and his co-workers have shown that Pflügge's evidence was incomplete and that under the usual conditions of humidity particles or droplets smaller than 0.1 mm. in diameter are evaporated completely before reaching the ground, leaving suspended nuclei consisting essentially of organic matter, salts and bacteria, to become, for all practical purposes, a part of the atmosphere. The survival of pathogenic microorganisms in such nuclei is, of course, largely a matter of their resistance to drying, and it has been shown that some of the respiratory pathogens, including viruses such as that of influenza, may remain viable and infective for many hours under these circumstances.⁵ The process of expulsion of such droplets in coughing, sneezing and talking has been photographed by Jennison⁶ and is illustrated in Fig. 30. Studies of the air in various types of rooms under various conditions have yielded data on the quantitative aspects of air contamination, green streptococci have been used as indicators of air pollution in much the same manner as *Bacterium coli* is used for studies on water pollution. In general, enormous numbers of bacteria of respiratory origin have been found in the air of crowded rooms, especially when the occupants are sneezing, and there can be no doubt of the significance of these observations in relation to the explosive spread of respiratory disease in a non-immune population.

Evidence has accumulated in recent years⁷ which strongly suggests that the inhalation of air-borne bacteria in dust may be an even more important factor in the dissemination of infectious disease of the respiratory tract than that of directly expelled infected droplets. The use of oiled blankets and floors under experimental conditions in hospital wards has, in a number of instances, proved a highly efficacious method of control of the spread of infection. The direct destruction of air-borne bacteria by the use of glycol and

The Rôle of Histamine in Anaphylaxis.—The evidence for the essential rôle of histamine in anaphylactic shock falls under four heads. Firstly, the likeness between histamine shock and anaphylactic shock, which we have already noted; secondly, the demonstration that tissues contain histamine that can be mobilized by suitable stimuli; thirdly, the demonstration of histamine mobilization during shock; and fourthly, the suppression of shock by measures that destroy or inhibit histamine or inhibit the reaction.

Lewis (1927), in his classical studies on the reaction of the skin to a localized stimulus or injury, was able to show that the local reddening, due to the dilatation of the minute blood vessels, and the succeeding local wheal, were independent of the local neuro-vascular mechanism, whereas the surrounding flare, due to the dilatation of the neighbouring arterioles, was dependent on a local axon reflex. He concluded that the reddening and the wheal formation were the result of a chemical stimulus provided by some substance liberated from the injured cells; and he found that histamine, alone among the many known substances that he tested, reproduced in complete detail the vascular changes, including increased capillary permeability, induced by the hypothetical cell constituent, which he referred to as the *H-substance*. Dale and his colleagues (see Dale 1929, Dale, Dudley and Thorpe 1927, Harris 1927, Thorpe 1928) showed that histamine is a normal constituent of many different tissues; and the evidence available strongly supports the view that it exists during life in an indiffusible form, from which it can be released without gross damage to, or death of, the cells that contain it.

The relative histamine content of different tissues is interesting and suggestive. Using a physiological method of assay (see Thorpe 1928, Harris 1927) the lungs have been found to contain between 35 and 75 mgm. of available histamine per kilo, the liver between 2.5 and 6.6 mgm., the skin as a whole about 6 mgm. (2.4 mgm. in the epidermis and 4 mgm. in the dermis). Other tissues contain much less. The voluntary muscles contain about 1 mgm. per kilo, the testis about 1.8 mgm., the submaxillary gland about 0.5 mgm., and the thyroid about the same. These figures are mainly for the organs of horse and ox. The histamine content of the different organs varies with the species of animal. Thus the skin of the rat contains 30–40 mgm./kg., but that of the guinea-pig only about 6 mgm./kg. Again, the blood of rabbits contains 1 to 5 μ g./ml., that of man and the guinea-pig less, and that of the dog very little. The blood histamine, it should be noted, is mainly in the granulocytes and platelets (see Code 1952). The plasma normally contains very little; free histamine is fairly rapidly destroyed by histaminase or diamine oxidase in the plasma.

after
in the blood, they calculated the amount present in the animals at the onset of shock and found it enough to account for the vascular reactions of the shocked animal. The substance was specifically destroyed by the enzyme histaminase (Dragstedt and Mead 1936b; see also Code 1939).

Watanabe (1931) obtained some evidence that the histamine content of the lungs of sensitized guinea-pigs was abnormally high, and much less in the lungs of animals after shock. Bartosch, Feldberg and Nagel (1932) were the first to demonstrate a histamine-like substance in the perfusate of sensitized guinea-pig lungs when antigen was added to the perfusion fluid. This observation was confirmed by a number of workers, and the identity of the substance with histamine more firmly established (see Schild 1939). Increased quantities of the histamine-like substance were also found in the blood of the whole guinea-pig after shock (Simons and Staub 1937, Code 1939). Large quantities of histamine are liberated from the liver of sensitized dogs, and heparin into the perfusate. Release is better when unclothed blood is used.

other bactericidal aerosols (p. 150) and ultraviolet irradiation is not only feasible in some circumstances but has given encouraging results.

Fig. 30 The atomization of mouth and nose secretions demonstrated by high speed photography. 1, A violent sneeze in a normal subject, note the close approximation of the teeth, resulting in effective atomization. 2, Head cold sneeze, note the strings of mucus and the less effective atomization of the viscous secretions 3, A stifled sneeze. 4, Sneezing through a dense face mask. 5, Cough, note the lesser discharge than in the uninhibited sneeze. 6, Enunciation of the letter f. (Jennison.)

Even though air-borne infection, whether by infected droplets or dust-borne bacteria, is an important factor in the spread of respiratory disease, very often direct contact with infected persons may assume a major role.

As may be inferred from the outline above, a disease not infrequently has

even how far we should locate the injury and liberation of histamine in one type of cell and the response to the liberated histamine in another. We have noted discrepancies between the relative histamine content of different organs and the damage they suffer in shock. There are other hints of a distinction between the source and the site of action of the liberated histamine; for example, isolated plain muscle from the sensitized dog gives no significant response to the specific antigen, but the plain muscle of the dog is sensitive to histamine.

We may now consider briefly the effect of anti-histamine substances on anaphylactic shock. Histamine is readily destroyed by the enzyme histaminase (Best and McHenry 1930). However, though Karady and Browne (1939) claimed to have protected sensitized guinea-pigs from shock by intravenous injections of the enzyme 15 minutes before the shocking dose, their findings were not subsequently confirmed (Knoll 1940, Rose and Browne 1941, Youngner, Freedman and Nungester 1941, Alexander and Bottom 1940).

A large number of substances have now been synthesized which inhibit the pharmacological action of histamine, some more specifically than others. Most of the more effective of these drugs diminish, and may even suppress, the symptoms of anaphylaxis in the experimental animal which are referable to free histamine. They do not affect sensitization; nor do they appear directly to affect the antigen, the antibody, or the antigen-antibody combination; and they act by neutralizing the released histamine. Much larger doses are usually required than those necessary to antagonize the estimated amounts of histamine released (see the review of Feinberg *et al.* 1950).

The administration of sublethal doses of histamine induces a state of increased tolerance to the drug. Farmer (1939) and Karady (1941) contend that histamine desensitization is accompanied by a moderate degree of desensitization to specific anaphylactic shock. Tell and others (1943, Rodney and Fell 1943) immunized rabbits with horse globulin coupled with the pharmacologically inactive *p*-aminobenzoyl histamine, and induced the formation of antibodies whose specificity was partly determined by the histamine. The immunized animals were then sensitized with ovalbumin. As compared with non-immune sensitized controls, there was definite evidence of a diminished liberation of histamine into the blood during shock, and of a diminished skin sensitiveness either to shocking doses of antigen, or to histamine. Immunized guinea-pigs, subsequently sensitized to ovalbumin, were largely protected against fatal shock. Coffin and Kabat (1946) confirmed this result, but found the effect to be non-specific, because immunization with unmodified horse protein was also protective.

The Rôle of Acetylcholine and other Endogenous Substances in Anaphylaxis.—Went and Lissak (1936, 1938) and Martin and Went (1939) reported that, during the perfusion of the heart of a sensitized guinea-pig with antigen solution, a substance resembling choline is liberated from the muscle, and that the heart muscle of sensitized guinea-pigs is more sensitive than the normal heart to the pharmacological action of choline. Went suggested that choline and acetylcholine, as well as histamine, may be liberated from different organs during shock. Wenner and Buhrmester (1937) found acetylcholine in the blood stream of rabbits after shock, but Ratnof (1939) could not confirm their findings. Kourilsky and his colleagues (1938) detected no acetylcholine in the hæmorrhagic lesions of shocked animals. They noted that acetylcholine produced no hæmorrhages in the tissues on local injection, whereas histamine did so. Nakamura and his colleagues pointed out that acetylcholine shock and anaphylactic shock have many features in common, but few in common with histamine shock, both in symptomatology and modification by physostigmine, eserine and other drugs. They attributed the main symptoms of anaphylactic shock to acetylcholine liberated as the result of antigen-antibody union in the region of the nerve-endings of the sympathetic system (Nakamura and Takahashi 1938, Nakamura 1941, Chigira 1941). Farber, Pope and Landsteiner (1944) were able regularly to demonstrate histamine in shocked guinea-pig lung; only in shocked heart

a certain epidemiological character which may at times be even more familiar to the epidemiologist than the causative agent is to the laboratory worker. In the case of epidemic influenza, for example, the disease is, at present, an epidemiological rather than clinical entity and is diagnosed with reasonable accuracy only during epidemic periods. Similarly, epidemiological studies have shown the existence of two kinds of smallpox, the one a relatively innocuous variety with a low case fatality and the other a severe disease (so-called malignant or "black" smallpox) with a high case fatality. The difference between these varieties is real and of no small practical importance even though indistinguishable by clinical observation of the individual case (p. 859).

The epidemiology characteristic of a given disease shows, on the one hand, certain, and sometimes close, relationships to other similar infections, and, on the other, a certain variability which arises as a result of transmission in more than one way. The enteric infections, cholera, typhoid fever and the bacillary dysenteries, are similar to one another in epidemiology but are quite different in this respect from the respiratory diseases or the insect-borne diseases. The epidemiology of typhoid fever, however, is variable within limits and depends to some degree upon whether the disease is water-borne, milk-borne or transmitted by food or contact. Clearly, then, although it is possible to speak of certain broad principles of epidemiology, the epidemiology of a disease is in itself a special case and must necessarily be considered elsewhere (see later chapters) under the head of that disease.

The epidemiological character of a disease is dependent primarily upon certain aspects of the microorganism and the clinical infection as indicated above, and secondarily upon the habits, environment and mass susceptibility of the host population. To return to the example of typhoid fever: any mode of transmission is necessarily one that provides a connecting link between infectious fecal matter and the mouth of a susceptible human being, and the possibilities are, to this extent, limited. The age, sex and seasonal incidence, to some extent the case fatality, and the geographical and sociological distribution of cases are reflections of both the mode of transmission and the character of the population. In the case of water-borne typhoid, the drinking water supplies the connecting link, and the ensuing epidemic, limited to the area supplied by the contaminated water, shows no respect for age, sex or economic status. Milk-borne typhoid, on the other hand, geographically limited by the route by which the infected milk is delivered, exhibits an increased incidence in the lower age groups and among females, and is somewhat more frequent among those of higher economic status. Other modes of transmission are similarly reflected as minor variations in the epidemiological character of the disease.

Although the characteristics of the infectious agent and the clinical disease determine the *means* by which disease may be transmitted, the *extent* of its spread is a mass phenomenon determined by the character of the host and parasite populations and, as a corollary, their interaction with one another.

The Bacterial Population. The well-known variation in the severity and "contagiousness" of the infectious diseases is a consequence of corresponding variation from one species of pathogenic bacteria to another in

of the earlier injections. The rabbit, as a whole, had become so sensitized that it reacted in this characteristic and abnormal way to the injection of the specific antigen at any site (see also Seegal, Seegal and Jost 1932, Davidoff, Seegal and Seegal 1932). This reaction, in its typical form, appears to be peculiar to the rabbit. However, similar local changes occur on injection of antigen into species like the guinea-pig, rat and dog, provided that an adequate amount of precipitating antibody is present in the circulation. The experimental preference for the rabbit is probably based upon the greater readiness with which this species forms suitable antibodies. There is intense inflammation at the site, characterized by adherence of polymorphonuclear leucocytes to the vessel walls, followed by migration into the surrounding tissues and the development of mural thrombi of leucocytes and platelets, and some necrosis of the endothelium of the arterioles and venules. After about 24 hours the polymorphonuclear response is gradually replaced by a less intense mononuclear cell infiltration, and a process of repair begins, accompanied by the development of multiple discrete foci of plasma cells (Gell and Hinde 1954).

Abell and Schenk (1938), by means of a transparent window grafted into rabbits' ears, observed that half an hour after introduction of the antigen there was an intermittent segmental spasm of the arterioles, which was soon followed by the histological changes outlined above. The cause of the arteriolar spasm and adherence of granulocytes to the vascular endothelium is not known, but when the invasion of the tissues by circulating granulocytes is prevented, much of the œdema and vascular damage characteristically seen in the reaction is eliminated (Stetson 1951; and J. H. Humphrey, unpublished).

The Arthus reaction appears therefore to have at least three components: (a) relatively rapid events whose visible effect is upon the local blood vessels but which do not by themselves cause extensive necrosis; (b) the formation of leucocyte-platelet thrombi and intense invasion of the tissues by polymorphonuclear leucocytes, which is accompanied by, and may actually be the cause of, œdema and necrosis of the vessel walls; and (c) a delayed infiltration by macrophages and histiocytes, which probably reflects the response of the body to a foreign protein localized by the allergic reaction, and may even lead eventually to antibody production at the site. It is possible, however, that this last stage represents a "tuberculin-type" of reaction (see p. 1329) due to the simultaneous existence of two types of hypersensitivity in the actively immunized animal.

The Arthus Phenomenon; Passive Sensitization.—The capacity to produce an Arthus reaction can be passively transferred by injection of precipitating antibody from the same or another species, and the intensity of the reaction produced is proportional to the amount of precipitin in the tissues (Culbertson 1935). The studies of Kabat and his colleagues (1947, Benacerraf and Kabat 1950) showed that, in the rabbit and guinea-pig, the reaction occurred when either the antibody or the antigen was introduced into the body first, and that the intensity of the reaction was proportional to the amount of antibody present, within a wide range of antigen concentrations, provided the amount of antigen was in excess of that required to neutralize the antibody. Minimal reactions were produced in the rabbit when 25 μ g. of antibody N were injected intracutaneously, followed half an hour later by antigen either intravenously or into the same site. In the guinea-pig, intravenous injection of 0.41 μ g. antibody N was sufficient to produce severe reactions, and of 0.09 μ g. to produce mild reactions, when followed by antigen intracutaneously half an hour later. These amounts are much larger than those required for sensitization to "immediate" anaphylactic reactivity (p. 1302). Unlike passive anaphylaxis, the capacity

their ability to invade the body tissues and, once established, to produce clinical disease. As indicated in a previous chapter, a single species is potentially variable in these respects, for such variation can be induced by appropriate experimental manipulation. The possibility of such intraspecies variation in a bacterial population existing under natural conditions is one that has intrigued students of infectious disease for many years.

It is tempting to account for the genesis and rise of epidemic disease by assuming that the causative agent of a disease of endemic proportions gains in virulence by successive passage from person to person until its pathogenicity is so enhanced that an epidemic ensues. Similarly, a sojourn in a host population containing an increasingly large proportion of immunes might be expected to result in a diminution in the virulence of the microorganism and consequent subsidence of the epidemic. Furthermore, successive epidemic waves might conceivably result from periodic fluctuations in the virulence of the parasite. Unfortunately for such an explanation, there is little or no direct evidence that alterations in virulence play an important part in the evolution of single or secondary epidemic waves, and, in nature, bacterial virulence appears to be a relatively stable character.*

On the other hand, differences in the severity of a single disease from one epidemic to another are, in part, attributable to the existence of strains of the infectious agent which differ from one another in virulence. Benign and malignant smallpox referred to above is a case in point, and some workers believe that some strains of the diphtheria bacillus produce a more severe disease, (i.e., with a higher case fatality) than others (p. 611). Although variable from one strain to another, available evidence indicates that within a single strain virulence does not fluctuate to a demonstrable degree.

Possibly attributable in part to alterations in bacterial virulence are the changes in morbidity and mortality of some diseases such as scarlet fever, syphilis and tuberculosis, over long periods of time. In the case of scarlet fever the twenty-five years prior to 1830 was a period of very low death rates and was followed by a forty-year period of high death rates. Since then the death rate has declined and, though the incidence remains high, the case fatality is relatively low. In other diseases only a decline has been observed. Syphilis is no longer the scourge it was in the sixteenth century, and the present decline in tuberculosis began before the institution of preventive and therapeutic measures. In still other diseases, such as measles, no such long-term alterations in prevalence have been observed. Information is as yet too limited to assess these phenomena; possibly in some diseases there are long-term periodic fluctuations in bacterial virulence (this may be an artifact and represent only variations in the prevalence of virulent "epidemic" strains of the parasite) while in others an adaptive reduction in virulence or increase in resistance on the part of the host or a combination of both may play a part.

In general, it may be said that, in the short view, the bacterial population, as it exists in nature, is remarkably stable in so far as its ability to produce disease in a host population is concerned. Although the severity of a disease

* Cf. Aycock, Lutman and Foley *Amer. Jour. Med. Sci.*, 1945, 209:395.

been given the name of "serum sickness." An excellent description of the disease and a detailed discussion of its significance are contained in the monograph of von Pirquet and Schick (1905), and in the review of Longcope (1943). The great extension of serum therapy in modern times has provided the data for large-scale surveys of the incidence and kinds of serum sickness (see Park 1921, 1928, Beer 1938, Lyall and Murdick 1938, Davis 1938, Rutstein *et al.* 1941, Kojis 1942). For our immediate purpose we need refer only to the following points.

The reaction must be distinguished from the disturbances of the thermo-regulatory mechanism, and the cardio-vascular reactions which are commoner sequels to the injection of serum. It occurs after primary as well as after subsequent injections. It is in no way related to the antibody content of the injected serum, but is a response to the foreign protein as such, which is usually horse serum. The reaction may occur within 2 hours of the injection of the serum, and up to 24 days after, though an incubation period of 8 to 12 days is commonest. Among the "immediate" reactors, there is often evidence of previous treatment with horse serum. Younger people are more prone than older, though the proneness may reflect the fact that younger persons are more liable to have had previous antiserum treatment, as compared with persons whose youth was passed in an age of less extensive serum therapy. The illness itself is characterized by rashes, especially of an urticarial type and often commencing at the site of the inoculation, by fever, joint pains, slight cedema without albuminuria (or with a mere trace of albumin in the urine), and by a varying degree of glandular swelling usually confined to the regional glands that receive the lymphatics from the site of inoculation. The illness is variable in duration, protean in its symptoms, and seldom of a serious nature, though it may be associated with severe discomfort. It is probably never fatal. The nervous system is affected, though rarely. The commonest lesions occur in the 5th and 6th cervical nerves. Neuritis is followed by flaccid paralysis of the muscles, with a slow and, in the greater proportion of cases, a complete recovery. Both motor and sensory nerves are affected. The neuritis may affect one or many nerves, and in some cases the lesions are more central and may even be cerebral. The neuritis is usually ascribed to an urticarial cedema of the nervous tissue (see Davis 1951). It should be noted that these paralyzes may follow the injection of other antigenic substances—vaccines and preparations of toxoid (see Kennedy 1929, Allen 1931, Young 1932, Doyle 1933, Ayer 1935, Wilkinson 1937, Bennett 1939, Hughes 1944).

In a tiny minority of cases an entirely different reaction follows the injection of serum, the patient dying within a few minutes with symptoms resembling those of acute anaphylactic shock. Park (1908) records two such cases among 50,000 persons who received serum injections in New York (see also Park 1921, 1928, Vance and Strassmann 1942).

Acute anaphylactic shock can also follow the injection of antigens other than serum proteins. There are, for example, a number of cases on record of shock after a second dose of a bacterial toxoid; the peptone used in the preparation of the toxoid appears to have been the responsible agent (see Parish and Oakley 1940, Werne and Garrow 1946).

We may note that processes which change the antibody globulin molecule in antisera from the horse also reduce their capacity to cause serum reactions. Thus, when proteolytically refined antisera (Chapter 7) are employed, the incidence of serum sickness and of sensitization to serum sickness, are reported to be greatly reduced (Pohacker-Fritsch and Siegl 1941, Kojis 1942, see also Coghill *et al.* 1940, Jones and Roberts 1941, Top and Watson 1941).

Experimental Serum Sickness and Related Phenomena.—The detailed study of the syndrome that follows the intravenous injection of a single large dose of a heterologous serum into rabbits was initiated by Rich and Gregory (1943), who

may, and often does, vary from one epidemic to another, variation in virulence is not an important factor in the single epidemic wave. Over long periods of time, however, alterations in virulence may contribute to the changes in morbidity and mortality observed in some of the infectious diseases.

The Host Population. In contrast to the relative stability of the bacterial population, the human population is highly variable in its resistance to infection, and the variation, attributable to both intrinsic and extrinsic factors, is not infrequently of such magnitude that its consequences are of considerable practical importance.

Since a population, human or infrahuman, is composed of individual organisms, it follows that its character is determined by the nature of these individuals and their relations to one another, and its reaction to an external influence is expressed in terms of the aggregate of the reactions of its members. The response of a human population to an infectious disease is, of necessity, measured in terms that are composites of the responses of the individual members of the population—in short, by some method of counting. Such counting is, of course, the basis of statistics, and the statistical method, with its ramifications and refinements, is a powerful tool which makes possible the study of the response of human populations to disease—a response which is measured in terms of rates, ratios, life tables and similar numerical devices.

Of the intrinsic factors which determine the response of a human population to an infectious disease, one of the most important is age distribution. The quantitative predominance of the lower age groups characterizing an immature population declines with population growth while the higher age groups correspondingly increase. As a consequence, the diseases of childhood and early adult life, such as diphtheria, tuberculosis and the like, are relatively prevalent in an immature population but become progressively less so with the passage of time, while the diseases of old age increase in incidence with the maturing of the population.⁹ The frequency of an infection is expressed as a rate, either as the number of persons infected in a given unit of time or *incidence*, or as the total number of persons infected at any one time or *prevalence*. Correction of morbidity and mortality rates is a practical necessity and is made either by the use of *specific rates*, i.e., the proportion of cases or deaths within a specified age group, or by the use of *standardized rates* which are not the observed rates but rather what the observed rates would be if the age distribution of the population were that of a standard or reference population.¹⁰

The sex distribution of a population and its racial composition are of somewhat lesser practical significance, although in some communities in the

⁹For a discussion of these problems see Perrott and Holland. *Milbank Mem. Fund Quart.*, 1940, 18 359.

and the populations of states or other portions of the country compared or adjusted to it.

certain persons develop a characteristic symptom-complex as the result of natural contact with some particular substance or range of substances. The substances that may evoke this response are of the most varied nature: in hay fever, pollens of various species; in asthma, pollens, horse dander or the cutaneous débris from other animals; in the food idiosyncrasies, a wide range of different materials; in the drug idiosyncrasies, a whole series of chemical compounds which have no common determinant structure.

One of the most striking features of the idiosyncrasies as a group is that—as in the anaphylactic reaction—the symptom-complex bears no relation to the particular type of substance by which it is evoked. In spite of the varied nature of the exciting materials concerned, the syndrome induced has an essential uniformity; though there are minor differences which seem to depend in the main on the particular route by which the reacting substance gains access to the tissues. It is particularly striking that, in the case of many drugs, the response exhibited by the hypersensitive subject—using hypersensitive in this particular sense—bears no relation to the pharmacological action of the drug in question. From among the drug idiosyncrasies, we must exclude those which are anaphylactoid, due in some cases at least to the capacity of the drug to release histamine from the tissues (see Schachter 1952).

The reactions induced may be either local or general. Among the former are the local reaction to the intracutaneous injection of horse serum or to the application to the skin of such a drug as iodoform, the coryza of hay fever and perhaps the associated asthma, and the acute vomiting and gastro-intestinal disturbance that follow the ingestion of a particular foodstuff. Among the latter are the generalized urticarial eruptions or oedema that may follow the administration by any route of a substance to which a person is hypersensitive, the occasional pyrexia, and the asthmatic symptoms that sometimes follow the entry of the exciting substance by a route other than the respiratory tract. There is also a group of delayed reactions in the skin, exemplified by the "contact dermatitis" following exposure to poison ivy and similar natural products, and to certain chemicals. It is of interest in this connection to note that with the displacement of serum therapy of bacterial infections by chemotherapy, serum sickness has largely been replaced by allergic reactions to the sulphonamides and the antibiotics (see, e.g., Florey 1952).

There are obvious points of similarity between this group of reactions on the one hand and anaphylactic hypersensitiveness on the other, but there are also obvious divergencies.

Among the points of similarity we may include the following (see Coca 1920a).

In both cases the reaction is specific. Although the naturally hypersensitive person may react to several different substances the range is usually limited, and may be confined to a single chemical substance. In both cases the type of response is essentially the same for a single animal species irrespective of the nature of the exciting substance. To this we may add refractoriness of the animal or tissues in which a reaction has been elicited to the same allergen, and in some cases, specific desensitization. We should note also that histamine release has been demonstrated from the blood and skin (Katz 1942), and bronchial tissues (Schild *et al* 1951) of allergic human subjects, on contact with antigen.

Among the features that have been held to distinguish the two conditions are the following. (1) The exciting agent in anaphylaxis is always an antigenic sub-

United States the high mortality rate of the Negro has necessitated the use of race-specific mortality rates.¹¹

The extrinsic factors which alter the resistance of a host population to the spread of disease may exert their effects in either or both of two ways: first, by influencing the resistance of part or all of the individuals comprising the population, and, second, by influencing the relationships between individuals. Perhaps the most important factor in the first category is active individual immunity. If a sufficient portion of a population is immune to a disease as a result of artificial inoculation or recovery from an attack, the resistance of the entire group to epidemics of that disease is of a high order, a phenomenon

Fig. 31. Changing age distribution in the population of the United States. Estimates 1940 to 1980 by Thompson and Whelpton.

which has been termed *herd immunity*. Other factors may reduce the resistance of the individual, in times of stress or calamity, for example, when relatively large groups are undernourished, fatigued and exposed to inclement weather, epidemic disease may spread with great rapidity.

Equally important to the resistance of a population to epidemic disease are the factors which determine the interrelationships of its members. Crowding in large gatherings or the enforced close association arising from inadequate housing facilities obviously provides opportunity for the dissemination of respiratory and other diseases transmitted directly from man to man, and, as well, certain indirectly transmitted infections, such as louse-borne typhus fever. Similarly, the spread of enteric infections is, to a large extent, dependent upon sanitary facilities and the solution of the twin problems of water supply and sewage disposal. Group practices which support a large rat popu-

¹¹ For a discussion of the methods of population study with respect to disease see Pearl: *Introduction to Medical Biometry and Statistics*, 3rd ed. W. B. Saunders Company, Philadelphia, 1940.

nitrogenous material is removed (Grove and Coca 1925). In these respects atopens do not differ essentially from antigens.

We have seen that many haptens, when injected intravenously into actively or passively sensitized guinea-pigs, will induce acute anaphylactic shock, and we might expect a similar phenomenon in natural hypersensitivity.

There remain instances of drug idiosyncrasies that are not so readily explicable along these lines, since the chemical structure of the exciting agent is not of the relatively complex kind which characterizes those haptens that are capable of inducing acute shock in a sensitized animal.

Numerous observations have, however, indicated a possible mechanism by which such simple compounds might come to function as complete or partial antigens. It has been found that animals may be sensitized by the injection of atoxyl and serum, or even of arsenical compounds alone (see Klopstock and Selter 1929, Mayer and Sulzberger 1931, Sulzberger and Mayer 1931); and it seems probable (Landsteiner and Levine 1930) that in such cases a preliminary union occurs between the simple arsenical compounds and some serum or tissue protein, with the formation of an effective antigenic complex. In later studies Landsteiner and Jacobs (1936) sensitized guinea-pigs with neoarsphenamine, and induced shock by the intravenous injection of guinea-pig serum mixed with arsphenamine, or arsphenamine alone. Jacobs (1932) succeeded in sensitizing guinea-pigs to iodinated sera by injecting them with guinea-pig serum mixed with Lugol's iodine solution, and suggested that a similar mechanism might be involved in the development of iodine sensitivity in man. Horsfall (1934) injected formolized rabbit serum into rabbits, and found that the animals developed skin sensitivity to uncombined formaldehyde. Landsteiner, as part of his investigations of experimental contact dermatitis, induced both skin sensitivity and anaphylactic sensitization by the intracutaneous injection of aromatic substances like picryl chloride and dinitrochlorobenzene (Landsteiner and Jacobs 1936, Landsteiner and Chase 1937) and non-aromatic substances like diazomethane and mustard oil (Landsteiner and di Somma 1938). These substances are all highly reactive and capable of forming conjugates with tissue proteins, and are also known to induce dermatitis or other forms of hypersensitivity in man (see, for example, Wedroff 1932; see also Landsteiner and Chase 1939, 1940b). From a study of the sensitizing action of tetryl (trinitrophenylmethylnitramine) in the skin of guinea-pigs, Gell (1944) concluded that this substance also acted by forming a picryl protein in certain tissues; though there was evidence that not all compounds of tetryl and guinea-pig protein would stimulate sensitivity, and that sensitivity was not necessarily associated with the presence of circulating antibodies to picryl protein. Gell and his colleagues called substances of this kind pro-antigens (see p. 302), whose antigenic potency among other things depended on their power to combine with tissue proteins. The substance 2,4-dinitrophenol is a pro-antigen, and in a study of eight homologous dinitrophenyl compounds, Eisen, Orris and Belman (1952) found that four, which combined irreversibly with skin proteins both *in vivo* and *in vitro*, were strong skin-sensitizing agents, and four which did not had no pro-antigenic activity. It may also be noted that though *p*-phenylenediamine induces skin sensitivity in guinea-pigs, the corresponding ortho- and meta-compounds do not sensitize; and substitution of $-SO_2NH_2$, $-CH_3$ or $-OH$ groups for the $-NH_2$ in the *para*-compound destroyed its sensitizing action (Nitti *et al.* 1937).

Mode of Sensitization in Man; Active and Passive.—The second differential criterion between hypersensitiveness and anaphylaxis is the mode of sensitization. There is no question that human hypersensitiveness occurs naturally and that hypersensitive reactions rapidly develop in persons with no *known* previous contact with the antigen eliciting the reaction. Nevertheless, there is good evidence that this condition frequently arises as the result of active sensitization.

lation make bubonic plague a potential menace, and the presence of large numbers of mosquitoes of the appropriate species allows the wide dissemination of malaria and yellow fever. These and other factors, political, sociological or economic in nature, obviously exert no small influence on the resistance of a population to the spread of disease.¹²

The Interaction of Host and Parasite Populations. It will be clear from the foregoing discussion that the interaction of the host and parasite populations is a highly complex phenomenon. Even assuming that the parasite population, when the parasite is a pathogenic bacterium, remains relatively constant in its ability to produce disease, the resistance of the host population is in a constant state of flux and the equilibrium between the two is rarely a "steady state." As has been indicated, the relation between host and parasite populations is a part of the general problem of interspecies competition, and has been studied at length, particularly by the economic entomologist¹³ and the experimental zoologist.¹⁴ The infectious diseases of man constitute a series of special cases of the host-parasite relationship, differing from one another with respect to mode of transmission, incubation period, period of infectivity, immunity, case fatality, etc. The studies on infectious disease have taken two forms. one, the theoretical analysis of epidemic spread; and the other, the experimental investigation of controlled epidemics among populations of laboratory animals, i.e., experimental epidemiology.

Theoretical Analysis. The theoretical treatment of the dissemination of infectious disease in a susceptible population is exceedingly difficult because of the tremendous number of variables which are involved. If, however, certain simplifying assumptions be made, analysis in terms of the mathematics of probability yields information of considerable significance, and a certain insight into the evolution of the single epidemic wave may be gained.

The evolution of the single epidemic wave is best considered here by the arithmetic method of Frost,¹⁵ which involves finite differences. Let C = the number of cases, S = the number of susceptibles and N = the contacts per day, then r , the contact rate per day, is given by

$$N = rCS \text{ or } r = \frac{N}{CS}$$

It is assumed that each case is infectious, that one contact suffices to produce the disease in a susceptible individual, that multiple contacts are disregarded, and that the unit of time (the day) is small enough so that C and S do not change materially during that period. Then the number of contacts per unit time t (the day) is

$$Nt = rCSt$$

The probability of contact is, therefore,

$$p = \frac{Nt}{S} = rCt$$

The detailed study of this passive atopic sensitization was taken up by Coca and his colleagues and by other investigators. Coca and Grove (1925) gave the name *atopic reagins* to the antibodies present in the serum of naturally hypersensitive persons, by which the specific hypersensitiveness can be passively transferred to the skin of non-sensitive persons. These reagins were demonstrable in the serum of all those subjects of hay fever or of asthma in whom the reaction to the intradermal injection of the specific atopen was positive. Not all normal skins were receptive, about 11 per cent. failing to react at all, and some 5 per cent. giving slight or doubtful reactions. The remaining 84 per cent. were fully receptive, and the local passive sensitization lasted for at least 4 weeks once it had been established. The reagin could be neutralized by the specific atopen in the test-tube, but gave no precipitin reaction *in vitro*, nor would it induce passive anaphylaxis in the guinea-pig. In a control series of experiments they noted that the normal human skin could not be passively sensitized to egg white or to ragweed-pollen with rabbit antisera, although these contained specific precipitins. Similar phenomena have, however, been noted in the case of passive anaphylaxis; neither horse antisera nor chicken antisera are effective in the passive anaphylactic sensitization of the guinea-pig, though antisera prepared in the rabbit are highly efficient from this point of view. Levine and Coca (1927) found that there was a proportional relationship between the degree of sensitivity of the skin and the reagin content of the serum in 33 cases of hay fever.

Clarke and Gallagher (1926) gave a very clear-cut demonstration of the latent period in passive atopic sensitization and of the *in vitro* neutralization of reagin by atopen without the production of any tissue reaction. They injected 0.05 ml. of atopen into one area of skin, and 5 minutes later they injected 0.05 ml. of reagin-containing serum into the same site and 0.05 ml. of the same serum into a second site some distance from the first. No reaction occurred after these injections, showing that the union in the tissues of atopen and reagin under conditions that give no time for the preliminary fixation of the reagin does not produce the typical response. Next day each site was reinjected with the same quantity of atopen. At the second site, where no atopen had previously been injected, a typical reaction occurred. At the first site no obvious response was elicited, showing that the reagin had been neutralized by the atopen that was present when the sensitizing injection was given.

Reagins and Antibodies.—As outlined above, the reagin differs from antibody in its inability to precipitate specifically with the atopen *in vitro*. Conversely, there is evidence that sera rich in precipitins are not necessarily effective skin-sensitizers.

Otto and Adelsberger (1931) observed that a typical reagin, from persons sensitive to horse dander, was very effective in sensitizing human skin, less so guinea-pig skin, and unable to sensitize guinea-pigs to anaphylactic shock; whereas the sera of persons suffering from serum sickness, or of man, rabbits and guinea-pigs that had produced antibody in response to injections of horse serum, were only moderately effective in sensitizing human skin but quite effective in sensitizing guinea-pigs, both locally in the skin, and to anaphylactic shock. On the other hand, Caulfeild, Brown and Waters (1937) were able to induce the same specific sensitization to extract of ragweed pollen in the skin of a normal person by serum from a hypersensitive person, and by serum from a guinea-pig immunized with ragweed extract; and Straus (1937) found that *rhesus* monkeys were readily sensitized by the injection of human sera containing reagins.

The experimental work with reagins is largely carried out, for obvious reasons, in skin. It should be noted, nevertheless, that passive sensitivity is conferred by the reaguic serum on many other tissues and organs as well (see Walzer 1941).

Skin-sensitizing antibody can also be induced in the rabbit (Cooke and Spain 1929). One pre-requisite for the production in these animals of sensitizing antibody

and the probability of avoiding contact is

$$q = 1 - p = 1 - rCt$$

Since there are $1/t$ units of time in the entire period, the chance of avoiding contact over this period is

$$Q = (1 - rCt)^{\frac{1}{t}} = e^{-rC}$$

Therefore, the chance of at least one contact is given by

$$P = 1 - e^{-rC}$$

and the number of new cases infected during the day is

$$PS = (1 - e^{-rC}) S$$

Assuming the incubation period to be one day—i.e., the contact of one day is the case of the next—a theoretical epidemic wave may be built up by a series of substitutions in the last equation. Starting with 10,000 susceptibles, one case, and a contact rate, r , of .0002, the first day,

$$(1 - e^{-.0002}) 10,000 = 2 \text{ (new cases).}$$

the second day,

$$(1 - e^{-.0006}) 9998 = 6$$

the third day,

$$(1 - e^{-.0018}) 9992 = 18$$

and so on through the complete epidemic wave. Various modifications such as limiting the period of infectivity through the introduction of case fatality and the development of immunity, extending the incubation period, and the like may, of course, be made. This kind of treatment is, of course, an application of the law of mass action. The first relationship, $N = rCS$, becomes $rCS = dC/dt$ and may be manipulated in a variety of ways. Wilson¹⁶ has developed this approach at some length.

Theoretical epidemics built up in this way show a remarkable similarity to observed epidemics of disease, and, although the factors entering into the determination of the value of r are highly complex, it is evident that the probability of chance contact is a factor of primary importance in the evolution of the epidemic wave. In a population consisting largely or entirely of susceptibles, this probability is large and the disease spreads rapidly, but, as the number of susceptibles is reduced by conversion to cases, immunes and fatalities, the probability diminishes and the epidemic subsides.¹⁷ It may be noted that the term "contact" is used to mean "effective contact" and more than one meeting with a case may be required to make up an effective contact. It is often said that an important factor in epidemic spread is dosage, i.e., the number of microorganisms that a susceptible individual encounters within a definite period of time. An adequate "dose" is, clearly, an effective contact.

¹⁷ For experimental studies on the mathematical theory of epidemics see Kermack and McKendrick *Jour. Hyg.*, 1939, 39:291 *et ante*. Also the summary by McKendrick: *Edinburgh Med. Jour.*, 1940, 47:117.

antibodies could sensitize guinea-pigs to anaphylactic shock with toxoid, but only the precipitin was active in passive Arthus sensitization. The non-precipitating antitoxin co-precipitated with the precipitating antitoxin, thus resembling the "univalent" antibody of Heidelberger (p. 290). Sherman, Menzel and Seebohm (1950) had earlier suggested that rabbit reagins might be "univalent" antibodies (but see Vaughan and Kabat 1953).

As we saw in Chapter 7, there is no reason to suppose that "univalent," or "low-grade," antibody differs essentially from precipitating antibody. Both are associated with the γ and sometimes the β globulin fractions of serum. Reagins, on the other hand, appear to be more commonly associated with α and β globulin fractions (Cooke *et al.* 1951, Campbell *et al.* 1954). They differ strikingly from precipitating antibodies in their affinity for skin tissue, and in heat lability. Heat lability, however, is not an invariable property; rabbit reagins are heat-stable (Sherman *et al.* 1948). Heat lability is tested in whole serum, and it is possible that heating does not directly destroy human reagin, but facilitates the formation of a complex with other serum proteins (cf. p. 252). Antitoxic reagin, indeed, is converted by heat into a specific blocking antibody (Kuhns and Pappenheimer 1952); and an analogous complex formation with serum albumin occurs when precipitating antitoxin is heated, rendering the antibody non-precipitating without affecting its antitoxic potency (Kuhns 1953).

We may, then, regard reagin as one of the general family of antibodies deficient in precipitating power, with physicochemical peculiarities that determine its readiness to adsorb to animal tissues, and, in certain species of animal, to form non-sensitizing complexes with other serum proteins under the influence of heat.

It must be emphasized that skin sensitivity can be induced by precipitating antibodies, and anaphylactic hypersensitivity by reagins. Moreover, the distinction on other grounds is by no means clear cut. We have noted that rabbit reagins are not heat-labile; and Chase (1947) found that hypersensitivity in guinea-pigs induced by simple but reactive chemicals, like picryl chloride, was transferable to normal guinea-pigs by the heat-stable anaphylactic type of antibody which nevertheless, like a reagin, sensitized the skin for periods up to 3 weeks.

We conclude therefore, that there is no case for the term atopen, as a name either of a class of substances distinct from antigens as a whole; or, since both reagins and precipitins may be induced by one and the same antigen, of a special class of antigens. There is perhaps a case for retaining the term reagin to denote non-precipitating antibodies inducing a relatively long-lasting hypersensitivity of the immediate type in skin and other tissues; but not as a name for a class of substances distinct from antibodies in general.

Natural blocking antibodies appear to be more closely related to the full precipitins, as are the blocking Rh antibodies to haemagglutinins (p. 245); they are probably distinct from the blocking antibodies made by heating antisera.

Passive Sensitization by Cells.—The immediate type of reactivity, as we have seen, is often transferable passively in the serum of the hypersensitive animal. Sensitizing chemicals, like the substituted chloro- and nitro-benzenes we discussed on p. 1320, may give rise to antibodies that induce in the normal animal an anaphylactic immediate-type skin sensitivity, which can be elicited by the chemical conjugated *in vitro* with a protein (see Chase 1947); but usually they induce in the actively sensitized animal a delayed type of sensitivity appearing in 5–20 days that is not transferable in the serum.

That sensitization of this kind is dependent on a systemic reaction in the animal was clearly demonstrated by Landsteiner and Chase (1940b), who failed to induce

The nature of herd immunity will become clear at this point, for the higher the proportion of immunes in a population the smaller the probability of effective contact between case and susceptible, *i.e.*, many of the contacts will be with immunes, and the population exhibits a group resistance to epidemic disease which may be of such a high order that an epidemic is no longer possible and the disease smolders in an endemic form as a result of the importation of new cases or the persistence of infection in healthy carriers whose contacts will give rise to an occasional case. A susceptible member of such an immune population, then, enjoys an immunity that is not of his own making but arises as a result of his membership in the group. A measure of this protection is given as Q in the above equations.

Fig 32. Diagrammatic representation of the course of an epidemic wave in terms of numbers of cases (lower curve) and numbers of susceptibles (upper curve). Note the coincidence of the peak of the epidemic wave with the threshold density of susceptibles (After McKendrick.)

Clearly there will be a critical proportion of susceptibles and immunes in the population, with a greater number of susceptibles epidemic disease can develop and with a lesser number it cannot. This critical point has been termed *threshold density* and is that which prevails at the peak of the epidemic wave. The total number of cases in the epidemic will, then, be twice the number of susceptibles in excess of this threshold density present at the beginning, and following subsidence of the wave the population is left with a greater or lesser degree of herd immunity.

Such precise relationships are only approximated in nature. In practice the threshold density fluctuates and is a function in part of dosage. When the prevalence of a disease is high a given individual will be subjected to a greater number of bacteria per unit time; some, previously immune to smaller doses, will become susceptibles under such circumstances and the

The Genetic Factor in Anaphylaxis and Hypersensitiveness.—The fourth character that has been held to distinguish human hypersensitiveness from anaphylaxis is concerned with the part played by inheritance in the two conditions. There is evidence (Cooke and Veer 1916, Coca 1920a, Spain and Cooke 1924, Clarke, Donnally and Coca 1928) that human hypersensitiveness tends to run in families. As regards the anaphylactic state, which among the allergies has been the most clearly established as due to an antigen-antibody reaction, we should expect that heritable variations in immunizability would be reflected not only in antibody formation but also in sensitization; and, as we saw in Chapter 42, there is evidence that responsiveness to antigens is heritable. But although in passive anaphylaxis the sensitivity is related to the amount of antibody employed, there is no evidence to indicate how far sensitivity is associated with the degree of *active* immunization, or whether such an association is hereditarily determined.

The incidence of natural human hypersensitivity is, of course, no direct measure of the proportion of the human race that has an hereditary disposition to sensitization. Among other things the opportunity for experience of the antigen, the intensity and duration of that experience, the nature and the route of entry of the antigen both as a sensitizer and an inducer of the sensitive reaction, will affect the issue. But when we can subject a sample of the population to a fixed sensitizing dose, we find a significant variation in response. In experimental sensitization of man with an extract of a *Primula* sp., for example, Bloch and Steiner-Wourlich (1926) observed that, whereas some persons were sensitized with one application, others required several applications.

With regard to the inheritance of human hypersensitiveness we have already noted (see Cooke and Veer 1916, Spain and Cooke 1924) that the genetic factor appears to be concerned with a tendency to develop reaginic hypersensitiveness in general, rather than a sensitiveness to any one antigen in particular. It appears to be unusual to find that parents and offspring, or even the same substance, or one may be sensitive to cat hairs, and so on. It is the type of hypersensitive reaction in general appears to be in some degree inherited; the tendency to develop asthmatic symptoms, for instance, being particularly frequent in certain families.

Among the 131 young adults they tested, Kuhns and Pappenheimer (1952) found 40 that were hypersensitive to diphtheria toxoid; of these, 35 (87·5 per cent.) had a personal or a family history of allergy. Put in another way, the incidence of hypersensitivity was 60 per cent. in 59 subjects with a positive history and only 7 per cent. in those with a negative history.

Landsteiner and Chase (1940a) report that guinea-pigs can by breeding be separated into strains of high and low susceptibility to sensitization by dinitrochlorobenzene, or to the atropens of poison ivy, thus affording one indication of a similarity between man and experimental animals in a heritable tendency to develop hypersensitivity.

There are insufficient grounds for postulating an essential difference between anaphylaxis and hypersensitiveness on the premises of our present knowledge of the influence of genetic factors in the two conditions.

Desensitization in Hypersensitiveness and Idiosyncrasy.

Specific Desensitization.—With regard to the fifth distinctive character, some observers, and particularly Coca (1920b), lay great stress on the difficulty of desensitization in the sensitive human subject as compared with its relative ease and

"effective concentration," so to speak, of immunes declines with consequent effect on the herd immunity to epidemic disease. This effect of dosage on the host population has been termed *infection pressure* and is a matter of considerable practical importance. Successive epidemic waves may, then, occur as a consequence of increased infection pressure as well as through the accumulation of new susceptibles (see below). Recurrent waves of a disease that is a clinical but not an etiological entity are, of course, another matter.

The question of the relationship between an infectious disease and a susceptible population over a long period of time is somewhat more complex. Mathematical treatment such as the Ross malaria equations and Martini's equations for immunizing diseases¹⁸ is too far removed from reality to have much practical significance, principally because the mathematical approach requires that the parameters remain constant over long periods of time. This condition is probably rarely if ever satisfied; it is well known, for example, that within the last century both diphtheria and scarlet fever, previously of low prevalence, took on a malignant character and higher prevalence for some decades and then within the last forty years have gradually declined in both prevalence and severity. It is of some interest, however, that the differential equations of Martini, for example, show one stable equilibrium at the origin and another at a positive value which is approached by a series of oscillations above and below the final state of equilibrium so that a series of epidemic waves appears. These solutions suggest that (a) under certain circumstances a disease may tend to die out and (b) under other circumstances a disease will reach an equilibrium after a series of epidemics of decreasing severity.¹⁹ Such periodicity in the incidence of many infectious diseases is well known, one of the best examples is that of measles which recurs in epidemic form at approximately two-year intervals. So far as is known, however, no infectious disease occurring under natural conditions shows a damped periodicity approaching invariability though it has been found to occur in experimental epidemics in which the immigration rate of the new susceptibles is very high (*vide infra*).

A disease will, of course, die out if it does not reproduce itself, i.e., if the bacterium is present only in the active case and each case does not, on the average, give rise to a second case. It is not unlikely that some diseases are dying out in this way, it has been suggested,²⁰ for example, that the decline in tuberculosis is due in part to inability of the disease to reproduce itself, a process accelerated by isolation of active cases. The second suggestion is of interest in connection with the epidemic periodicity of certain diseases such as measles, which appears in epidemic form usually at two year intervals. It is obvious, of course, that following an epidemic a new crop of susceptibles appears, and when their numbers reach a sufficiently high level, a new epidemic ensues and so on *ad infinitum*. It is unlikely, however, that these epidemic waves are damped as predicted by theoretical equations, for subtle variation in the complex of factors that are oversimplified as parameters

¹⁸ For a discussion of this general problem see Lotka: *Elements of Physical Biology*. Williams & Wilkins Company, Baltimore. 1925.

¹⁹ See Wilson and Worcester: *Proc. Nat. Acad. Sci.*, 1945, 31:294.

²⁰ Frost: *Amer. Rev. Tuberc.*, 1935, 32:644.

Delayed reactions of the tuberculin type are definitely diminished, even by relatively small doses of the hormone (Long and Favour 1950, Long and Miles 1950, Harris and Harris 1950). There is in rabbits an associated suppression of the characteristic reticulo-endothelial cell reaction (Gell and Hinde 1951; see also Osgood and Favour 1951).

Sensitization of guinea-pigs to tuberculin is also decreased by cortisone, but the capacity of lymphocytes to transfer hypersensitivity is not altered (Cummings and Hudgins 1952). (For other references, see the review of Kass and Finland 1953.) The action of cortisone is obscure. Long and his colleagues (see Long 1954), who described in guinea-pigs a tuberculin desensitization by ascorbic acid, sought to relate it to control of amino-acid metabolism, which in turn affects the oxidation of ascorbic acid and the accumulation of glucose-1-phosphate, an intermediate of carbohydrate metabolism; experimentally the phosphate ester proved to be a powerful desensitizing agent.

Summarizing, it appears that reactions involving a proliferation of mesenchyme cells, whether antibody-forming cells during sensitization, or the inflammatory cells associated with delayed-type reactions, are diminished by the hormone; but that the immediate, purely exudative reactions are little altered. In any event, the reaction of antigen with antibody does not appear to be affected.

ALLERGIC REACTIONS IN BACTERIAL INFECTIONS

The term *allergy* is almost impossible to define precisely. We use it in a loose, but widely accepted sense to cover a group of reactions characterized by a heightened or accelerated response to a particular type of antigen, irrespective of the balance of harm, or benefit, that the altered response confers on the allergic host.

All the phenomena of hypersensitivity could obviously be included under this general label. In the present section we are concerned with those instances in which an allergic state develops in relation to a bacterial infection.

It has already been noted that bacterial haptens may induce acute anaphylactic shock in a sensitized guinea-pig; but before discussing allergic reactions in the wider sense we may refer briefly to anaphylactic sensitization with bacterial antigens.

Active anaphylactic sensitization has been induced with various bacterial antigens and passive sensitization with the corresponding antibodies (Rosenau and Anderson, 1907 Kraus and Doerr 1908, Holobut 1909, Kraus and Admiridzibi 1910, Zinsser and Parker 1917, Tomesik and Kurotchkin 1928, Lancefield 1928, Enders 1929, Avery and Tillet 1929), or by Dale's technique with the isolated uterus (Zinsser and Parker 1917, Zinsser and Mallory 1924, Tomesik and Kurotchkin 1928). The reactions are specific and desensitization can be demonstrated. Sensitization to bacterial antigens cannot, however, be produced with the same ease as can sensitization to such antigens as horse serum or egg white. A single injection of bacteria frequently fails to produce any demonstrable sensitization, and the most successful results have been obtained by giving repeated small injections of antigen, followed by an interval of three weeks or so before the intravenous injection of the test dose, which should be relatively large. A technical difficulty in work of this kind is introduced by the fact that many of the bacterial suspensions employed are themselves toxic when administered in any considerable dose, and the symptoms that develop in normal animals after the injection of massive doses of bacteria or bacterial products may be very similar to anaphylactic shock. The difference in the response of normal and of sensitized animals may, therefore, be relatively difficult to detect.

will wipe out the damping effect. It will probably be many years before predictions regarding the future of infectious diseases attain a status better than that of guesses.

Experimental Epidemiology.²¹ The information that may be derived from observation of naturally occurring disease, i.e., descriptive epidemiology, is limited since the observer has no control over the process and for all practical purposes the experiment is carried out for instead of by him. In experimental epidemics, however, the conditions may be adjusted as desired and it may be anticipated that such experiments will be highly informative.

In recent years the study of epidemics of infectious disease developed in populations of laboratory animals under controlled conditions has been carried out by Topley, Greenwood, Wilson and others in England and by Webster and his colleagues in the United States.²² These experimental epidemiological studies have been confined, for the most part, to the study of the dissemination of *Salmonella typhi-murium* (aertrycke), *Salmonella enteritidis*, *Pasteurella muriseptica* and the virus of ectromelia (a foot-pad disease of mice) among populations of mice. Mouse typhoid and pasteurellosis are regarded as analogous to human diseases such as typhoid fever in which there is an imperfect immunity and carrier state, and ectromelia as analogous to human diseases in which a solid immunity is developed, such as diphtheria. The extent to which the analogies may be carried, and to which the conclusions reached are applicable to the considerably more complex human population as it exists under natural conditions, is open to some question, nevertheless, these studies, as yet in their infancy, have yielded valuable information.

The experiments which have been carried out were of two general types. The closed epidemic was produced in a population of mice, often about fifty in number, by the introduction of infected animals. The other type of experiment was carried out in an infected mouse population recruited by continuous immigration, i.e., mice were added at regular intervals, the rate varying from one mouse every three days to six mice per day. The results may be summarized briefly:

(1) The epidemic wave initiated in the closed population by the introduction of infected individuals closely resembled those observed in the human population.

(2) The effects of dispersal of the infected population of the closed epidemic into large or small groups at various times during the development of the epidemic were studied. The time at which the population was dispersed was found to be of primary importance; the later dispersal was effected, the less favorable the result, and after the peak of the epidemic wave was reached it continued unchecked even though the population was dispersed to individual mice. This is of particular interest since fleeing from an epidemic has been a popular method of escaping infection, viz. the *Decameron*. In this connection the results of dispersal of children from the industrial centers of England in 1939-1940 may be noted. A sharp reduction of 40 per cent or more in diphtheria morbidity occurred in the evacu-

²¹ See the general discussion by Topley: *Proc. Roy. Soc., Ser. B*, 1942, 130-337.

a relatively short interval a local chancre does not develop (Truffi 1910); but reinfection with a different strain may induce a typical local lesion (Kolle and Schlossberger 1926). Brown and Pearce (1921) infected a number of rabbits and treated some of them with arsphenamine shortly after the development of the primary chancre. Five days later these rabbits were injected with the same strain of *Trep. pallidum*. Most of the treated animals developed chancres. The untreated animals did not.

Kolle (1922, 1924) treated rabbits with neosalvarsan at various stages of infection. He found that rabbits treated within about 6 weeks after the initial infection usually responded to a subsequent injection by developing a new chancre. When treatment was delayed beyond this point, reinfection seldom gave rise to a chancre. When treatment was delayed for about 3 months a new chancre could very rarely be produced. Rabbits that were treated and reinfected at long intervals after the primary infection (75-250 days) were not, however, completely resistant to reinfection (see Kolle and Prigge 1927, 1929). Tissue extracts from treated rabbits that had not been reinfected were non-infective for normal rabbits, but similar extracts from treated and reinfected rabbits gave rise to characteristic lesions, showing that the spirochaetes had gained access to the tissues and were presumably multiplying in them, at least to a limited extent. On these grounds Kolle and his colleagues maintain that the immunity to reinfection displayed by rabbits that have been treated in this way is only a "chancre immunity." The exact significance of this term is a little dubious. We have noted many examples of a partial antibacterial immunity in which bacteria may persist for long periods in the tissues without giving rise to any of the lesions that they produce in non-immunized animals. Moreover, the evidence suggests that a more complete immunity against *Trep. pallidum* may be induced under optimal conditions. Uhlenhuth and Grossmann (1928) treated syphilitic rabbits with neosalvarsan 107 to 506 days after the primary infection. Attempted reinfection 3 to 10 months after treatment gave rise to no obvious lesions; and in only 4 of 11 rabbits could spirochaetes be demonstrated in the tissues.

The results of experiments where the cures were obtained with the more efficacious penicillin even more clearly indicate an immunity persisting after the destruction of the spirochaetes (see Chapter 81; and, for a comparable state of affairs in a bacterial disease, brucellosis, see Pollack *et al.* 1952).

The point at issue is not whether immunity to reinfection, and "symptom-immunity," exist in animals with demonstrable infection; that is clearly established: but whether immunity is necessarily dependent on the infected state. As Staritsky (1948b) points out, in proofs based on demonstrable susceptibility of apparently cured animals and the refractoriness to reinfection of those thought to be infected, there is sometimes a circular argument wherein animals proving susceptible to reinoculation are assumed to have been cured of the first infection, and those proving refractory are assumed still to be infective.

(This discussion of infection immunity, it should be noted, is confined to bacterial diseases. In Chapter 55 we discuss a well-established type of infection immunity which so far has proved characteristic of virus diseases—where the infection of susceptible cells by one virus may prevent their infection by a second virus; here the immunity appears to result from the occupation by the first virus of certain key metabolic processes of the host cell upon which both viruses depend for their proliferation.)

In summary, we may say that immunity to reinfection appears to be established within a short time after the appearance of the initial lesion. At this stage the maintenance of immunity is associated with the maintenance of infection; complete chemotherapeutic cure may be followed by a return of susceptibility. But after a longer period of infection a partial immunity is established that may persist after complete chemotherapeutic cure, and, after still longer periods of infection, a complete immunity may be established that is independent of the persistence of infection.

ated towns together with an increase of 60 to 70 per cent among local children in reception centers, the latter returning to normal within six months. Similarly, the biennial periodicity of measles was broken by this dispersal.²³

(3) The effect of active immunization on the epidemic was not so great as might be supposed. If the mice were immunized prior to the epidemic, a favorable effect was apparent and more marked in ectromelia than in *S. typhi-murium* infections. Immunization undertaken after the initiation of the epidemic was without effect.

(4) In the mouse population recruited by continuous immigration a series of epidemic waves developed, the frequency of which was directly related to the rate of immigration. Thus, with a low rate, such as one mouse every three days, epidemic waves were separated by periods of remission in which no deaths occurred. As the immigration rate was increased, the waves occurred with greater frequency and with the addition of six mice per day there were no periods of complete remission, the epidemic waves taking the form of periods of increased mortality.

(5) With high immigration rates, the peaks and troughs in the daily death rate became less and less pronounced after a year or more, both the rate and total population tending to become invariant. Thus it was possible to approximate experimentally the damped periodicity and eventual equilibrium predicted on theoretical mathematical grounds (see above), and the experimental host population could be brought into approximate equilibrium with the parasite population.

(6) An inadvertent experiment with a population recruited by a high rate of immigration proved to be of considerable interest. The mouse population had reached the equilibrium indicated above by summer when there was a heat wave of unusual intensity in London. There were many non-specific deaths (mice are highly susceptible to heat), followed by violently fluctuating specific mortality. In the course of time an equilibrium was again reached but at a considerably higher death rate and decreased numbers than formerly. The parasite was shown to be unaltered in virulence and the immigrants had not, of course, had the heat experience. Hence the host-parasite relationship *per se* was altered by an environmental "catastrophe." The relationship of these observations to the long term relation between the human population and infectious disease is of interest. If it be assumed that the day of the mouse is equivalent to thirty days in the life of man, over the four years taken by this experiment the following were observed: (a) a period of stability with low regular death rates and growing population (ca. 600 days) equivalent to a human experience of slightly less than fifty years—this, it may be noted, is longer than the twenty-five year period ending about 1830 during which the death rate from scarlet fever was relatively low; (b) a period equivalent to fifteen years of severe and repeated epidemic waves; and (c) a period equivalent to some thirty years of relatively high mortality in a more or less stable state of equilibrium in a population reduced in numbers—it may be noted that the post-1830 epoch of virulent scarlet fever lasted more than forty years.

(7) The mortality rates of the mice were intimately related to the length

²³ Stocks: Jour. Roy. Statistical Soc., 1941, 104:311, *ibid.*, 1942, 105:259.

sensitized cells, protects the antibody that is fixed to the cells, except when an excess of antigen is injected.

The difference between the anaphylactic and immune state is quantitative rather than qualitative, depending upon the balance between circulating and fixed antibody.

(6) Many of the most dramatic features of the syndrome of anaphylactic shock are the result not of the antigen-antibody reaction itself but of the liberation, among other substances, of histamine by the injured cells, and the consequent response of the histamine-sensitive cells throughout the body. The histamine acts chiefly upon the vascular endothelium, promoting exudation of blood fluids; and upon smooth muscle, making it contract. Acute local reactions may be elicited in the tissues of anaphylactically sensitive animals. Isolated preparations of smooth muscle like the intestine react to antigen by contraction; and local regions of the skin of the intact animal react by increased permeability of the blood vessels and acute exudation of blood fluids.

(7) The sensitized animal may be desensitized by the injection of the specific antigen in amounts too small to induce acute shock or by a route that ensures slow absorption so that there is no rapid transport to the circulating blood.

(8) A variety of substances, when injected intravenously, give rise to a syndrome resembling, in many but not in all particulars, that of anaphylactic shock. The resemblance of these anaphylactoid reactions is not due to any similarity in the underlying mechanism, but to the fact that, in each case, cellular injury is followed by the liberation of histamine and other substances, and this by the characteristic syndromes of histamine shock.

(9) In man, the "immediate" type of hypersensitivity, corresponding to acute anaphylactic hypersensitivity, is induced by certain drugs; by antigens such as pollen, horse serum and horse dander; and by bacterial proteins. It is found characteristically in hay fever, in some cases of asthma, and in urticaria. The antibody concerned is often non-precipitating, with a high tissue affinity ("reagin"). It is detected by passive transfer to normal skin, which then acquires a local specific hypersensitivity.

Sensitizing chemicals like picryl chloride, and plant substances from *Primula* spp. and poison ivy, become antigenic by forming complexes with the body proteins, and so induce hypersensitivity. They induce a delayed reaction on application to the skin. Combination with the skin proteins may in part explain the delay, because these substances elicit immediate reactions when conjugated *in vitro* with protein. The antibodies concerned may be either precipitating or non-precipitating. In some cases sensitivity can be passively transferred by the serum, in others, it is transferable only by lymphocytes.

In these natural allergies, temporary desensitization by treatment with antigen is induced with greater difficulty than in experimentally produced hypersensitivity.

(10) The Arthus reaction, induced by repeated intracutaneous injection of antigen into one site, is characterized by a massive granulocyte reaction and severe damage to blood vessels, and appears to depend on the intravascular combination of antigen with antibody. A similar localization of the antigen-antibody combination is associated with the development of the various vascular lesions found in serum sickness.

(11) Specific hypersensitiveness may also develop in the course of natural or experimental bacterial infection. This type of hypersensitivity is characterized by

of time that they were members of the infected population; the rate rose rapidly to a peak in the early days of cage age and, although it declined slowly with the passage of time, to a greater extent in ectromelia than in mouse typhoid or pasteurellosis, the survivors of one epidemic wave may be the victims of another. The removal at regular intervals of a number of mice equal to the number added at the same intervals markedly altered the trend of these mortality rates; under these circumstances, the initial peak of mortality was lower, but the rapid decline was not apparent and the mortality rate remained at a high level.²⁴ Removal was of considerable advantage to the individual mouse; in general, the earlier the removal the greater the advantage, except during the decline of an epidemic wave, when isolation did not increase the chances for survival of individual animals.

Although the evolution of the single epidemic wave in the experimental studies closely resembles its counterpart in the human population, the inability to control experimental epidemics by immunization is at variance with observations on epidemic disease in human populations. Some human diseases, such as diphtheria and smallpox, can be restrained from assuming epidemic proportions by active immunization of a sufficiently large number of the individuals making up the population. Whether or not this and certain other minor discrepancies prove to be real or illusory with future work, a number of pertinent suggestions have come out of these investigations. The response of the experimental host population in terms of mortality rates and cage life expectation cannot be interpreted as yet in some cases; in others the interpretation is questionable. For example, the English workers feel that some of the data suggest alterations in virulence and "infectivity" of the bacteria, while Webster in the United States interprets these findings as indicative of a graded, inheritable resistance in the host population.

Some of the experiments, however, have yielded clear-cut results that bear directly upon the interaction of host and parasite populations in nature. Perhaps the most important of these is the experimental demonstration of recurring epidemic waves resulting from the continuous addition of new susceptibles to the infected population. In spite of the fact that such a sequence of events is predicted by theoretical epidemiology, as indicated above, the repeated flaring up of a disease of man or domestic animals, thought to be stamped out in the inter-epidemic periods, is most often taken as evidence of the reimportation of infection.²⁵ The experimental demonstration of this

ated towns together with an increase of 60 to 70 per cent among local children in reception centers, the latter returning to normal within six months. Similarly, the biennial periodicity of measles was broken by this dispersal.²³

(3) The effect of active immunization on the epidemic was not so great as might be supposed. If the mice were immunized prior to the epidemic, a favorable effect was apparent and more marked in ectromelia than in *S. typhimurium* infections. Immunization undertaken after the initiation of the epidemic was without effect.

(4) In the mouse population recruited by continuous immigration a series of epidemic waves developed, the frequency of which was directly related to the rate of immigration. Thus, with a low rate, such as one mouse every three days, epidemic waves were separated by periods of remission in which no deaths occurred. As the immigration rate was increased, the waves occurred with greater frequency and with the addition of six mice per day there were no periods of complete remission, the epidemic waves taking the form of periods of increased mortality.

(5) With high immigration rates, the peaks and troughs in the daily death rate became less and less pronounced after a year or more, both the rate and total population tending to become invariant. Thus it was possible to approximate experimentally the damped periodicity and eventual equilibrium predicted on theoretical mathematical grounds (see above), and the experimental host population could be brought into approximate equilibrium with the parasite population.

(6) An inadvertent experiment with a population recruited by a high rate of immigration proved to be of considerable interest. The mouse population had reached the equilibrium indicated above by summer when there was a heat wave of unusual intensity in London. There were many non-specific deaths (mice are highly susceptible to heat), followed by violently fluctuating specific mortality. In the course of time an equilibrium was again reached but at a considerably higher death rate and decreased numbers than formerly. The parasite was shown to be unaltered in virulence and the immigrants had not, of course, had the heat experience. Hence the host-parasite relationship *per se* was altered by an environmental "catastrophe." The relationship of these observations to the long term relation between the human population and infectious disease is of interest. If it be assumed that the day of the mouse is equivalent to thirty days in the life of man, over the four years taken by this experiment the following were observed: (a) a period of stability with low regular death rates and growing population (*ca.* 600 days) equivalent to a human experience of slightly less than fifty years—this, it may be noted, is longer than the twenty-five year period ending about 1830 during which the death rate from scarlet fever was relatively low; (b) a period equivalent to fifteen years of severe and repeated epidemic waves, and (c) a period equivalent to some thirty years of relatively high mortality in a more or less stable state of equilibrium in a population reduced in numbers—it may be noted that the post-1830 epoch of virulent scarlet fever lasted more than forty years.

(7) The mortality rates of the mice were intimately related to the length

of time that they were members of the infected population; the rate rose rapidly to a peak in the early days of cage age and, although it declined slowly with the passage of time, to a greater extent in ectromelia than in mouse typhoid or pasteurellosis, the survivors of one epidemic wave may be the victims of another. The removal at regular intervals of a number of mice equal to the number added at the same intervals markedly altered the trend of these mortality rates; under these circumstances, the initial peak of mortality was lower, but the rapid decline was not apparent and the mortality rate remained at a high level.²⁴ Removal was of considerable advantage to the individual mouse, in general, the earlier the removal the greater the advantage, except during the decline of an epidemic wave, when isolation did not increase the chances for survival of individual animals.

Although the evolution of the single epidemic wave in the experimental studies closely resembles its counterpart in the human population, the inability to control experimental epidemics by immunization is at variance with observations on epidemic disease in human populations. Some human diseases, such as diphtheria and smallpox, can be restrained from assuming epidemic proportions by active immunization of a sufficiently large number of the individuals making up the population. Whether or not this and certain other minor discrepancies prove to be real or illusory with future work, a number of pertinent suggestions have come out of these investigations. The response of the experimental host population in terms of mortality rates and cage life expectation cannot be interpreted as yet in some cases; in others the interpretation is questionable. For example, the English workers feel that some of the data suggest alterations in virulence and "infectivity" of the bacteria, while Webster in the United States interprets these findings as indicative of a graded, inheritable resistance in the host population.

Some of the experiments, however, have yielded clear-cut results that bear directly upon the interaction of host and parasite populations in nature. Perhaps the most important of these is the experimental demonstration of recurring epidemic waves resulting from the continuous addition of new susceptibles to the infected population. In spite of the fact that such a sequence of events is predicted by theoretical epidemiology, as indicated above, the repeated flaring up of a disease of man or domestic animals, thought to be stamped out in the inter-epidemic periods, is most often taken as evidence of the reimportation of infection.²⁵ The experimental demonstration of this

²⁴ Greenwood, Hill, Topley and Wilson: Jour. Hyg., 1939, 39.109.

²⁵ In this connection Major Greenwood (*Epidemics and Crowd-Diseases*. The Macmillan Company, New York, 1935) has made the following delightful suggestion: "... a majority of the officials who in different countries report upon epidemics among farm animals cannot bring themselves to conceive that upon a farm or within a district wherein a scheduled disease once existed, and was afterwards officially declared to have ceased to exist, it could start into life without a reimportation of *materies morbi*, these happenings must be explained by reimportation. We can always see a joke much more easily when it is against some poor foreigners rather than against ourselves. I advise an Englishman, therefore, to read the Dutch or German explanations of the recrudescence of foot and mouth disease and learn how the virus may be blown by the winds of heaven, or dropped on an island in the excreta of wild geese. A Dutchman might find explanations of the reimportation of foot and mouth disease to be found in English official documents equally bizarre."

phenomenon and the indicated futility of quarantine in the control of a disease which has become widely disseminated (only when a disease is not present, or present in limited effective foci, can quarantine and isolation procedures be effective) is, clearly, of considerable significance.

Epidemiological Data and Their Interpretation. The purposes of epidemiological study are threefold: first, to indicate the nature of the infective agent, its source and modes of transmission when these are not fully established otherwise, i.e., on an experimental basis; second, to extend this information into a corresponding general theory of the epidemiology of the disease; and third, to determine in detail the local conditions which favor or control the dissemination of the infection in a given area or community.

For these purposes four general types of information, usually simple in character but wide in extent, are required. First, the *area* in which the disease occurs and the regularity of its geographical distributions are highly informative. Thus, the general occurrence of a disease indicates that environmental conditions, including fauna, climate, etc., peculiar only to parts of the area are not essential to its transmission. Similarly, restriction of the disease within geographic limits indicates that special environmental conditions are necessary for its dissemination; these may include crowding, presence of an insect vector, water supplies, proximity to reservoirs of infection, etc. In general, a uniform distribution of the disease is indicative of a simple method of transmission, as in the case of measles, whereas an irregular distribution, such as that of spotted fever, implies a more complex process dependent upon a source of infection or conditions necessary to transmission that are correspondingly irregularly distributed.

Second, the *rate of prevalence* of the disease suggests the source of infection. A high rate, such as that of measles, indicates that the observed cases are the most important, if not the only source of infection. Conversely, sporadic distribution of widely separated cases implies the existence of a concealed reservoir of infection such as the casual or chronic carrier or some of the lower animals.

Third, the *seasonal distribution* is also informative when considered together with other epidemiological features of the disease. Thus, a seasonal occurrence may be consistent with hypothesized insect transmission or it may eliminate an insect vector as the sole transmitting agent. Similarly, the occurrence of water-borne typhoid fever in the late winter and early spring supports the hypothesis of preservation of typhoid bacilli in the cold and their liberation from contaminated watersheds in the first thaws.

Lastly, the *age distribution* of the disease is suggestive as a corollary to other epidemiological characteristics, and often aids in their interpretation. Thus, a disease occurring for the most part in the early years of life, such as measles or diphtheria, often shows differences in age incidence between urban and rural areas which are explained by the more frequent occurrence of immunizing infections, apparent or subclinical, in the more crowded areas. Since similar differentials are apparent in poliomyelitis, the age distribution of this disease, together with other of its epidemiological features, supports the view that this disease is widely prevalent as a subclinical infection.

CHAPTER 52

CERTAIN NON-SPECIFIC MECHANISMS IN GENERAL IMMUNITY

THE protective mechanisms we have discussed in the preceding chapters are specific in their action. Whether established by nature or by art, they increase the resistance of the body against some particular bacterial infection, not against bacterial infections in general. In the present chapter we shall consider certain mechanisms from which this element of specificity is absent.

Many of these non-specific activities cannot be easily related to defence as a whole. Often they relate to little more than the observation of an antibacterial action by body fluids or tissues, or by their derivatives; and even when the antibacterial element in the system under observation has been identified with some precision, we may be unable to estimate its significance, either quantitatively or qualitatively, in natural infection. Sometimes the activity is lacking in certain animals—as for example in the breed of guinea-pigs without complement in the blood we noted in Chapter 42—or it may be associated with a resistant species of host, thus enabling us to estimate its relation to immunity; but such estimates must be made with caution, because the differences we observe may be accidental, or associated with unrecognized changes in other more important elements of the defence system.

Thus uncertainty limits us in this chapter mainly to description. It is an uncertainty that characterizes many investigations of non-specific mechanisms. By contrast, the certainty of the many conclusions we have drawn about specific immunity is a measure of the ease with which we can investigate substances, such as antibodies, that have nicely distinguished specificities.

Blood Factors

β -Lysins, Leukins and Plakins.—Among the earliest records of experimental immunity are some observations on anthrax infection, which established clearly the presence in the serum of certain animal species of bactericidal substances different in kind from the bactericidal complex formed of specific sensitizer and complement. Thus the serum of the rat is actively bactericidal for the anthrax bacillus, and this activity remains after heating the serum at a temperature of 56–60° C. for 30–40 minutes (von Behring 1889, 1892, Malvoz 1902, Pirenne 1904). The name *β -lysins* has since been applied to these relatively thermostable bactericidal serum constituents.

Other early investigations showed that similar thermostable bactericidal substances could be extracted from suspensions of polymorphonuclear leucocytes. Like the *β -lysins*, these *leukins* are restricted in their range of activity, some bacterial species, in particular the spore-bearing aerobes such as *B. anthracis* and

Epidemiological evidence, therefore, consists of a series of inter-related facts from which a conclusion or series of conclusions may be drawn. The first step in epidemiological procedure is necessarily the demonstration of associations between the frequency of occurrence of the disease and some conditions or set of conditions, the second the ascertaining of the relationship of these associations with one another, and third their relations to the general epidemiological theory of the disease. To take a simple example, in milk-borne typhoid fever it may be ascertained that cases of the disease occur predominantly along the route of the milkman, that in families so supplied the cases occur among those who drink milk, that the cases appeared within a limited time to suggest simultaneous infection and that an employee of the dairy is a carrier of typhoid bacilli. Not only are these associations related to one another but they are consistent with the general epidemiological theory of typhoid fever, viz., that transmission is basically a matter of the transfer of infected fecal material (or urine) from a case or carrier to the mouth of a susceptible person.

While this would appear self-evident, there is an opinion of some prevalence that since epidemiological evidence is necessarily purely circumstantial, it cannot be conclusive. This is perhaps due in large part to failure to appreciate the development, often basically statistical and therefore mathematical, of the logical analysis, and the significance of the body of evidence as a whole. The method of analysis and interpretation of epidemiological evidence is identical with that of experimental evidence, the practical difference lying in the fact that, as pointed out earlier, the epidemic is an experiment done for rather than by the observer and cannot be manipulated.

The Control of Infectious Disease. With an understanding, albeit admittedly imperfect, of the factors which determine the means and extent of the dissemination of infectious disease, comes the possibility of control. The variety of epidemiological types of disease and the individual variability within these broad groups make for differences in control measures, and the control of a given disease under given circumstances almost always constitutes a special case. Certain generalizations may, however, be made which will serve to indicate the complex nature of the problems of the control of the spread of infection and provide a point of departure for consideration, in later chapters, of specific diseases.

In general, control measures may be regarded as corollaries of the factors involved in the transmission of infection and, therefore, fall into two groups: one including those which raise the resistance of the individual and, through him, of the population; and the other, those designed to alter the relationships of the individual members of the population to one another in such a way that the opportunities for the dissemination of the infectious agent are reduced. Very often both types of control measures are used, their relative efficiency and practicality varying from one disease to another.

Diseases of lower animals which are transmitted either directly or indirectly to man involve a third population, the animal reservoir of infection. When transmission is from animal to man and occurs only rarely from man to man, three methods of control are possible. First, the disease may be controlled in the animal, second, the relationship between the human and

activity of leucocytes, in both phagocytosis and chemotaxis (Delaunay and Pagès 1946, Delaunay *et al* 1951).

Clearly there exist in the normal sera of certain animal species bactericidal substances which are non-specific in their action, in the sense in which immunological specificity is generally understood—though their range of activity is limited by the varying sensitiveness of different bacterial species—and which are not increased in amount as the result of immunization. Bactericidal substances having very similar properties may be extracted from leucocytes and perhaps from blood platelets.

The relation of these substances to effective immunity is by no means clear. To take the case of anthrax, the relatively resistant rat has β -lysins in its serum; so has the susceptible rabbit, but the relatively resistant dog has none (see Ledingham 1922). The significance of the leukins and plakins is still more difficult to assess. They are not identical with leucocytic enzymes (see Fleischmann 1928), though the participation of extracellular enzymes of this kind in leukin action cannot be excluded. That the antibacterial substances present in or derived from leucocytes play some part in resistance to infection seems highly probable; but we do not know whether their rôle is primary or secondary, nor how it is related to other defence mechanisms.

Tissue Factors

Antibacterial Substances in the Tissues.—Bactericidal substances have been sought for in normal tissues, in attempts to explain their natural immunity, and in infective tissues, in attempts to explain the destruction of bacteria that often follows the local reaction to invasion.

Nutini and Lynch (1946) added extracts of brain and spleen to cultures of toxigenic *Staph. aureus*, and obtained a non-toxigenic variant; they also found that the extracts protected mice to some extent against infection with a toxigenic staphylococcus. Micks, Whitney and Anigstein (1951) isolated from hydrolysed human and cattle red cells a polypeptide which cured streptococcal infection in mice. Bloom and his colleagues (see Bloom and Prigmore 1952) obtained substances, either basic proteins or polypeptides, active in varying degree against *B. anthracis*, other *Bacillus* spp., *Bact. coli* and *Str. pyogenes*, from the thymus, pancreas, thyroid and other mammalian organs. The authors assigned a prominent rôle to the anthracidal factor in immunity to anthrax (see Chapter 76). Another tissue constituent, the basic protein spermine, is bacteriostatic and sometimes bactericidal for a number of bacteria (see Rozansky *et al* 1954). Hirsch and Dubos (1952, Hirsch 1953) isolated it from kidney, and found it to have a powerful bacteriostatic action on the tubercle bacillus *in vitro* when activated by another tissue constituent, spermine oxidase. It was less effective on saprophytic mycobacteria. They also extracted a tuberculostatic basic polypeptide from the thymus, spleen, and pancreas of the calf. It was not present in calf lung or liver, suggesting that its distribution in various organs might be inversely related to the distribution of tubercles in the natural disease (Dubos and Hirsch 1954; see also Bloom *et al* 1953, Fletcher *et al* 1953). Tuberculostatic substances have also been described in the lymph nodes, spleen and liver of tuberculous animals (Soltys 1953). Lewis and Schwartz (1949) briefly reported the *in vitro* killing of *Str. pyogenes* by an extract of rat liver. The factor was not present in other rat organs tested and did not affect three other species of bacterium examined.

Very little can at present be said about the significance or mode of action of these tissue substances in immunity; we may note, nevertheless, that many of them, like the antibiotics derived from bacteria (p. 189), are basic peptides.

animal populations may be altered in such a way that transmission of infection cannot take place; and third, the resistance of the human population may be raised by immunization procedures. The relative efficacy of these methods of control is variable and depends upon the disease. Rabies, for example, can be controlled in the dog population, and, in fact, has been entirely eliminated in England by rigid regulation, but neither mass immunization of the human population nor alteration of the relationship between dog and human populations is practical. In the case of bovine tuberculosis and undulant fever, however, disease may not only be controlled in the animal population, but the relation between human and animal populations is readily altered by interposing the barrier of pasteurization. In other instances in which the reservoir of infection is a wild animal, immunization, when a solid immunity can be obtained, of the limited number of individuals who have contact with such infected populations is satisfactory.

The insect-borne diseases present still other problems in control in that the link between man and animal or man and man is a living organism. In general, control of the insect population or of the disease in the insect will result in control of the disease in man. The infections transmitted by insects are, for the most part, rickettsial, protozoan and virus diseases, few bacterial diseases are insect-borne, presumably because in many of the blood-sucking insects the intestinal tract is actively bactericidal and most species of bacteria are rapidly destroyed there. The mechanical transmission of bacterial infection by insects is, then, relatively rare and, except under unusual circumstances, of no great importance. Two species of pathogenic bacteria are, however, resistant to this bactericidal activity: the bacilli of plague and tularemia multiply in the rat flea (*Xenopsylla cheopis*) and the deer fly (*Chrysops discalis*) respectively. When the microorganism either multiplies or completes a portion of its life cycle in the insect vector, the insect is infective for the duration of its life; such is the case in yellow fever, typhus fever, malaria and other diseases. The problems of control of these diseases are the problems of the control of the insect population, either indirectly through the insect's animal host as in bubonic plague or directly as in malaria. A further complication is introduced in the case of spotted fever. The tick (*Dermacentor andersoni*) undergoes an incomplete metamorphosis, and the infection is "hereditary," i.e., transmitted to the second generation. There is, in consequence, not only an animal reservoir of infection but also a second reservoir in the form of infected ticks.

Diseases Transmitted Directly from Man to Man. The diseases transmitted directly from man to man by contact or by air-borne infection are by far the most difficult to control. The mechanism of transmission is, of course, very simple and does not offer the possibilities for interference that may be taken advantage of in the more complex processes. Furthermore, the practices and habits of the human population that make possible transmission by these means are a part of day-to-day existence in the life of man. Thus the aggregation of human beings under crowded living conditions in urban areas, and the theatres, schools, churches, and other public meeting places cannot be dispersed or eliminated for the control of air-borne infection. Similarly, pre-

Ingestion of the bacterium is not necessarily followed by its digestion. This is especially true of virulent forms; for example, virulent tubercle bacilli (Fell and Brieger 1947, Suter 1952) and brucellæ (Dickey and Forbus 1945) remain alive for some time inside the intact phagocyte. Rogers and Tompsett (1952) observed that, once inside the phagocytes, both virulent and avirulent staphylococci decreased in numbers, beginning 10-15 minutes after ingestion; the number of avirulent cocci remained low for 24 hours but the organisms of the virulent strain began to multiply after 4-8 hours.

Although growth of bacteria within the phagocyte in all probability leads to its death, in certain circumstances it appears that phagocytes may eject the ingested organisms in a viable state and themselves remain viable (Wilson 1953).

The continued survival of a bacterium in an intact free phagocyte, which moves in the tissues and reaches the lymph and blood vessels, may lead to the dispersion of the organisms to other parts of the body. This is not necessarily a failure of defence, as it is sometimes assumed to be, because, as we argued in Chapter 47, dispersion of the invader may have survival value for the animal, in this case by ensuring that the bacteria carried in the microphages ultimately reach the highly efficient macrophages of the reticulo-endothelial system.

The migratory power of the phagocyte, especially chemotactic migration in response to substances elaborated at the immediate site of infection, is clearly an important part of its antibacterial function, and both macrophages and microphages display this chemotropism (see Lasfargues and Delaunay 1947, Harris 1953).

These powers are affected by bacterial products. Thus, the *in vitro* migration of white blood cells into clotted plasma is inhibited by virulent, but not by avirulent tubercle bacilli; and by *Salm. typhi* and *Ps. pyocyanea*, but not by *Staph. aureus* or Type III pneumococcus. The crude endotoxins of *Salm. typhi* and *Ps. pyocyanea* also inhibit migration, but the type pneumococcal polysaccharide does not (Martin *et al.* 1950, Martin and Chaudhuri 1952). Elberg and Schneider (1953) observed a similar inhibition by brucella cells and endotoxin. Chemotactic migration also is reported as being inhibited by a lipid fraction (Allgower and Bloch 1949) and by the antigenic polysaccharide (Choucrour *et al.* 1951) of the tubercle bacillus. An adaptive response to the inhibitory effect may well take place in the infected animal, because leucocytes can be made refractory to the anti-migratory action of virulent tubercle bacilli by prior treatment of a donor animal by the organisms given intravenously (Martin *et al.* 1950), and to that of various species of *Brucella* by infection with the corresponding species (Elberg and Schneider 1953).

It remains to note some instances of non-specific increase in resistance to bacterial products. Rabbits and men, on repeated intravenous injection of small doses of enterobacterial endotoxins, acquire a tolerance to the pyrogenic effects of such doses; rabbits have also been shown to acquire tolerance to the gross toxic effects of larger doses. The tolerance, which disappears some days after the cessation of the repeated injection, is non-specific, being unrelated to the antigens in the various preparations. It is apparently due to an increased efficacy of the clearing and detoxifying mechanism of the reticulo-endothelial system, and is abolished by intravenous thorotrast and other blocking agents (Beeson 1947a, Morgan 1948, Bennett and Beeson 1953). A similar tolerance of rabbits to the provocative effects of these substances in the Shwartzman reaction (see next section) is also induced by their repeated intravenous injection.

The Bactericidal Power of the Blood.—This leads us to a consideration, necessarily brief, of the possibility of inducing an effective immunity by increasing the non-specific bactericidal mechanisms of the cells and fluids of the body. A. E. Wright

vention of the spread of venereal disease is theoretically possible but relatively unsuccessful in practice.

In the past, therefore, control of disease spread by these means has been dependent upon effective active immunization procedures. Diphtheria and scarlet fever may be so controlled by the immunization of a reasonably large part of the population, but influenza, the common cold and others continue to be widespread.

With the elucidation of the mechanisms of air-borne infection and the development of aerosols (p 150) and ultraviolet irradiation for the destruction of air-borne bacteria, it seems possible that the spread of air-borne infection may be controlled. Thus, the establishing of air sterilization in public gathering places of various kinds, possibly in the air conditioning systems, as well as in hospital wards may be effective.

The control of the spread of a given disease is, in practice, complicated by two important factors. First, a disease is often transmitted in more than one way. This variation may be within narrow limits, for example, an insect-borne disease may be transmitted by several species of insects which differ from one another in distribution, breeding habits and the like. In extreme cases a disease may fall into more than one epidemiological type; bubonic plague, for instance, which is transmitted from the rat to man by the rat flea, may assume a pneumonic form transmitted by infective droplets and become independent of the rat population. Secondly, infection may be carried and transmitted, not only by clinically recognizable cases of disease but also by cases before clinical symptoms appear; by individuals who have a disease in such a mild form that it is not recognized, and by healthy individuals who carry the infection either transiently or semipermanently. For example, while it is not difficult to prevent epidemics of water-borne typhoid fever, the disease remains endemic in a community as a result of the dissemination of the bacilli from ambulatory cases and carriers, and this so-called "residual typhoid" is extremely difficult, if not impossible, to eradicate.

It will be clear from the foregoing discussion that the transmission of infection is indeed a highly complex matter. Each disease is a special case of the host-parasite relationship which is not infrequently complicated by the interaction of two or more host populations. The elucidation of the interrelationships of these groups is a necessary preliminary to the understanding of the mechanisms operative in the dissemination of disease.

Cowan (1939) immunized rabbits with *Past. pseudotuberculosis* and found that the rate of disappearance from the blood of intravenously injected *Staph. aureus*, both immediately after injection and after establishment of the secondary bacteraemia (see p. 1191), was greater than that in normal animals, and equal to that in rabbits immunized with *Staph. aureus* vaccines. In view of the complete antigenic dissimilarity of the pasteurella and the staphylococcus, this effect is clearly non-specific. In this connection we may note that Day (1942, 1944) reported an increased immunity of mice to pneumococcal infection by inoculation with extracts of a wide variety of cocci and bacilli. Day, however, regarded the immunity as induced by a common antigen. As we saw on p. 1345, certain antibacterial mechanisms are stimulated, apparently non-specifically, during the course of naturally occurring disease in man—notably an increase in the bactericidal power of the blood associated with fever, possibly due to an increase in substances resembling β -lysin.

Taking the evidence as a whole, it would seem that non-specific stimulants of this class are for the most part too slight or too transient in their effect on resistance to be worth exploiting as prophylactics against infection. The transience of the effects is clearly no bar to their use in the therapy of established infections, where such stimuli might be beneficial, especially in the early stages of the disease; but little has been done in this direction. (The anti-infective action of hormones and ionizing radiations is discussed in Chapter 51)

The Shwartzman Phenomenon.

In the preceding paragraphs we have considered various reactions that are associated with a non-specific increase in resistance. In concluding this chapter it will be convenient to refer briefly to an experimental procedure that is associated with a localized and non-specific increase in sensitivity. Shwartzman (1923, 1929a, b, 1931, 1932, 1933) described a curious phenomenon that has become known by his name, which has been studied in considerable detail (e.g., Gratia and Linz 1931, 1932, Gross 1931, Freund 1934a, b, Freund and Smith 1934, Freund and Hosmer 1935, Morell and Shwartzman 1938, Alechinsky 1938, 1939, Weir 1938, Ayo 1943). The earlier work is fully discussed in Shwartzman's monograph (1937).

When a rabbit is injected intradermally with a small amount of a filtrate of a culture of *Salm. typhi*, and 24 hours later is injected intravenously with the same filtrate, the intravenous injection is followed, within a few hours, by the development of a hæmorrhagic lesion at the site of the intradermal injection. It is not, however, necessary that the same organism should be used for the intradermal injection and for the subsequent intravenous injection, or that the organisms used for the two injections should be antigenically related. Filtrates from, or suspensions of, a variety of bacteria will sensitize the skin to the intravenous injection of an equally wide variety of bacteria or bacterial filtrates. Not all bacteria contain effective sensitizing substances, nor is the local sensitizing effect the result of a simple inflammatory reaction. Thus (Shwartzman 1923), the injection of uninoculated culture media, of turpentine or of filtrates of various strains of streptococci, failed to sensitize the skin to the subsequent intravenous injection of filtrates of typhoid cultures. The sensitizing or, as Shwartzman prefers to call them, the "preparatory" substances are thermostable, antigenic, of relatively large particle size and often closely associated if not identical with the "complete antigens" or endotoxins of coliform and salmonella bacilli. Purified preparatory substances are said to produce no detectable change in the tissues. Not all Gram-negative bacteria contain preparatory substances (see Witebsky and Salm 1937, Wise and Kerby 1943). Nevertheless, the vascular endothelium is in some way altered by the preparations so that the intravenous "provoking" dose causes severe hæmorrhage and necrosis in the prepared site.

Chapter 10

THE BACTERIOLOGY OF WATER AND SEWAGE

Of the interrelationships between the members of human populations that facilitate the transmission of infection, those arising as a consequence of common water supplies and the group disposal of sewage are among the most important. *Transmission of disease by this means is, of course, confined to diseases of the so-called enteric group, in which infection takes place via the gastro-intestinal tract and the causative microorganisms are discharged with the feces. Infection is, therefore, the result of a direct connection between infectious fecal material and the mouth of a susceptible person, and when that connecting link is a common water supply, as it frequently is, outbreaks of cholera, typhoid fever and the like occur. This link is, however, readily broken; the great water-borne epidemics are rapidly becoming a thing of the past as a consequence of the utilization of effective control measures, and present day water-borne epidemics are indicative, not of a lack, but of a failure to make use of existing knowledge.*¹

WATER²

Because of water-borne disease and the obvious desirability of its control, studies of the bacteriology of water have been directed, for the most part, toward its sanitary aspects. The best single criterion by which the sanitary quality of a water may be judged is, clearly, the kind and numbers of bacteria that are present in it. If it were possible, as a routine procedure, invariably to detect the presence of the appropriate disease-producing bacteria, it would be unnecessary, from the sanitary point of view, to take the non-pathogenic forms into consideration. *This is, however, not the case, a judgment of the sanitary quality of a water cannot be made on the basis of failure to find a microorganism such as the typhoid bacillus in that water. This bacterium, for example, is usually so outnumbered by similar forms such as the colon bacillus that its isolation and identification require enrichment cultures in selective media and other time-consuming procedures and even then are not always successful, and a negative finding is of doubtful value.*

It is legitimate to assume, however, that when a water is polluted with human fecal material, it is probable that it contains bacteria which cause enteric infection. This probability becomes a certainty when the fecal material is pooled, as in the sewage of a community, because of the ubiquitous presence of healthy carriers of typhoid bacilli and similar microorganisms. Since it is im-

¹ Gorman and Wolman: *Jour. Amer. Water Works Assn.*, 1939, 31:225.

² Prescott, Winslow and McCrady: *Water Bacteriology*. 6th ed. John Wiley and Sons, New York. 1946.

decrease the power of leucocytes to migrate in clotted plasma. This decrease occurs in the leucopenic period after the provoking dose. Moreover, the leucocytes of Shwartzman-refractory animals are unaffected by a provoking dose (Berthrong and Cluff 1953, Cluff 1953). That the local vascular occlusion by clumped cells and fibrin is a necessary feature of the reaction is evident from the effect of heparin, which in high anticoagulant doses maintained for 4 hours after provocation, completely inhibits the reaction (Good and Thomas 1953, Cluff and Berthrong 1953). It does not affect the change in the migrating powers of the leucocytes, noted above. Thomas and Stetson (1949) suggest that local preparation may activate a protease at the site, which is held in check by protease inhibitors until the latter are destroyed by the provoking factor of toxin. They observed an analogous reaction when a provoking factor was injected one hour after an intracutaneous dose of papain (see also Christensen 1952).

The occlusion of glomerular capillaries that characterizes the generalized reaction is not cellular but hyaline, but, as in the local reaction, the participation of leucocytes in the formation of the hyaline material is suggested by its absence in nitrogen-mustard treated animals (Thomas and Good 1952).

The possibility that in natural infections there may be local alterations in the reactivity of tissues, particularly of vascular tissues, induced non-specifically by substances of bacterial origin, cannot be overlooked in our attempts to analyse the phenomena of resistance to infection. Thus, the hæmorrhagic episodes in certain chronic infections of man may be related to the phenomenon (see Shwartzman *et al.* 1936). There is ample ground for speculation, but little direct proof.

Local infections with a variety of bacteria—*e.g.* streptococci and the tubercle, anthrax and influenza bacilli—are preparatory in the Shwartzman sense. A general infection with Group A streptococci prepares for a generalized reaction, but *in vitro* streptococcal cultures, or parts thereof, are not preparatory (Thomas *et al.* 1953). However, extracts of streptococcal skin lesions from the rabbit will prepare normal rabbits, so that a Shwartzman-like reaction can subsequently be provoked by streptococcal culture filtrates rich in streptolysin O (Schwab *et al.* 1953). As we have seen, some pathogens contain both preparing and provoking factors; these possibly operate as such in natural infection, to the detriment of the infected animal. For example, Cohen and Moolten (1943) found both factors in a virulent strain of *F. necrophorus*, but preparatory factors only in an avirulent strain. In rabbits infected intratracheally with the latter, the intravenous injection of provocative factors, derived either from the virulent strain or from the meningococcus, precipitated a fatal infection.

The generalized Shwartzman reaction may be inadvertently elicited in man; thus, Love and Driscoll (1945) report a fatality following two injections of a typhoid vaccine separated by a 24-hour interval. But aside from a possible connection between hæmorrhagic phenomena in certain chronic infections in man (see Shwartzman, Klemperer and Gerber 1936) it is at present impossible to say what part this mechanism plays in natural infection and resistance, or in artificial immunization.

SUMMARY

(1) In addition to the specific factors that determine antibacterial immunity, there are certain non-specific factors which appear to play some part in the reaction of the tissues to invading bacteria. The significance of these factors in general defence is difficult to assess.

(2) The blood plasma in certain animal species contains antibacterial substances, usually thermostable, of which the β -lysinins are an example. Their bactericidal action is limited to particular bacterial species, and it seems doubtful whether they confer an effective immunity even against these. They are not

practical to isolate these pathogenic bacteria themselves as a routine measure, some indicator of fecal pollution will serve equally well as a criterion of the sanitary quality of a water. The question, which was stated many years ago,³ becomes this: Are there types of bacteria which are never present in natural waters free of pathogenic bacteria but which may always be found in water polluted with human fecal material and therefore probably with pathogenic bacteria? If so such types of bacteria can be used as indicators of pollution. The answer to this question involves a consideration of the bacterial flora of natural waters, including both bacteria which are native inhabitants of water and those microorganisms whose presence is a consequence of contamination from external sources.

Bacteria Native to Natural Waters. The bacteria whose native habitat is water are not well known,⁴ in part because many of them are difficult to grow on laboratory media. There is no question, however, of the existence of a bacterial flora normal to and characteristic of natural waters. The types of bacteria which make up this natural population may be considered briefly:

- (1) *higher bacteria*, frequently the sheathed forms assigned to the *Chlamydo-bacteriales* and including sulfur, iron and other forms,
- (2) the *Caulobacteria*, a relatively recently described group of "stem" bacteria which occur in lakes and other bodies of water attached to some inanimate object
- (3) the *spiral forms*, which are frequently found in great numbers in water, some of which may be very large, 20 to 30 μ in length, as compared with the parasitic spirilla:
- (4) a variety of *bacilli*, including
 - (a) pigmented forms such as *Bacterium prodigiosum*, *Bacterium violaceum*, *Bacterium aureum*, and others,
 - (b) various non pigmented forms such as
 - 1 the fluorescent bacteria—*Pseudomonas fluorescens*,
 - 2 certain of the sulfur bacteria,
 - 3 thermophiles,
 - 4 aerobic, spore forming bacilli of uncertain taxonomic position,
- (5) *coccus forms*, both
 - (a) pigmented, generally yellow—very often *Sarcina lutea*, and
 - (b) non pigmented—*Micrococcus aquatilis*, *Micrococcus caudicans*, and others,
- (6) *nitrogen fixing bacteria*—*Azotobacter aquatilis* in particular.
- (7) *nitrifying bacteria*—both *Nitrosomonas* and *Nitrobacter*.

These water bacteria are found in fresh water in swamps, streams and lakes. The bacterial populations of salt waters have not been studied until recent years, but it appears⁵ that the sea contains similar bacteria, including the nitrogen fixing forms, the fluorescent bacteria, various pigmented forms and

like, and each instance of contamination or possible contamination must be considered individually. Fecal bacteria have been found to penetrate from 100 to 200 feet in ground water.⁸ In general fine soils and sand tend to impede their progress to a greater extent than coarse sand and gravel. The rock formations may be of considerable significance; sandstone, for example, filters out bacteria, while limestone tends to erode with the formation of direct communicating channels, and wells drilled into such formations may contain typhoid bacilli which entered the water many miles away and are, therefore, always to be regarded as dangerous.

Contamination by Human Excreta. Contamination of water by human excreta may take place, not only indirectly through the agency of soil as noted above, but also directly. Such direct contamination is, for the most part, a consequence of human population densities and urban organization, and takes the form of dumping of sewage of one community into a body of water which serves as a water supply to another. Whether directly or indirectly contaminated, such waters contain not only the native bacterial flora supplemented by microorganisms from the soil, but also the bacterial flora of the human intestine. The contribution of the last consists primarily of *Bacterium coli* in very large numbers, together with *Clostridium welchii*, *Streptococcus fecalis* and the various intestinal pathogens.

Factors Influencing the Kinds and Numbers of Bacteria. The numbers of bacteria that may be found in a given water are dependent primarily upon the type of water, whether it is a surface water, such as that found in streams, lakes and shallow wells, or a deep water from deep driven wells. In the first instance opportunities for contamination are great and, as might be expected, many bacteria are present. The water from deep wells, on the other hand, has undergone an effective filtration in order to reach the deeper strata in which it is obviously not subject to any extensive contamination; hence relatively few bacteria are found.

A variety of environmental factors influences the bacterial content of water; chief among these are the amount of organic matter present and the temperature. In general, the more nutriment there is present in the form of organic matter, the greater the number of bacteria. Low temperatures are not conducive to rapid growth and tend to keep the numbers of bacteria down, a factor that favors the survival of pathogens such as the typhoid bacillus which are unable to multiply in any case. Higher temperatures result in an increase in bacterial numbers in the presence of sufficient organic matter, but if the supply of nutriment is not great, after a preliminary increase during which the food supply is exhausted, the numbers fall below the initial level. Other environmental factors are not infrequently influential in determining the types of bacteria present in a water; thermophiles will, of course, predominate in hot springs and sulfur bacteria in sulfur springs; and the acidity of many natural waters results in a limited flora of acid-resistant bacteria.

Bacteria in Ice.⁹ Although it is difficult if not impossible to sterilize a substance by exposure to low temperatures, many of the bacteria present are killed, only the resistant cells surviving. The great majority of bacteria in water are

⁸ See, for example, the studies of Caldwell Jour. Inf. Dis., 1938, 62:225, 272

CHAPTER 53

LOCAL IMMUNITY

THE defence mechanisms with which we have hitherto been concerned have for the most part been generally effective throughout the tissues of the host; and by whatever route bacteria or their products gain access to the tissues these mechanisms will tend to protect the body as a whole.

Another type of immunity may be conceived, confined to one particular area of the body, or to one particular kind of tissue. In Chapter 45 we have discussed certain mechanisms that hinder the access of bacteria to the tissues, many of which, like the lysozyme in the conjunctival sac, or the acidity of the gastric juice, are functions of a particular locality in the body. We may distinguish these from the mechanisms of local immunity which we consider in this chapter, by assuming that they act on the infecting organism before it gains its primary lodgment in the tissues. It will be clear, nevertheless, that the distinction, though convenient, is arbitrary, for the hindering mechanisms may in fact be located in the tissues; and even if their action, like that of gastric juice, takes place manifestly outside the tissues, the effect is ultimately dependent on local tissue function. We must, therefore, be prepared if necessary to accept a superficial hindering mechanism of this kind as an expression of a true local immunity, though we shall in the meantime confine ourselves to manifestations of resistance within the tissues.

An enhanced local resistance may or may not be associated with a significant increase in the resistance of the body as a whole; moreover, it may depend on a local variation in the response of a generalized defence mechanism; or upon the reaction of special tissues or types of cell in the area under consideration. There has been a tendency to confuse the issue of local versus general immunity by inadequate definition of the problem to be solved. The concept of a local immunity as such has been imperfectly separated from hypotheses regarding the mechanism on which it depends. In some cases the term has been used as though it implied a tissue or cellular immunity, not conditioned by humoral factors. In others there has been a failure to distinguish clearly between specific and non-specific effect. It will simplify discussion if we consider the available evidence from each point of view in turn.

What evidence is there for the existence of a local as opposed to a general immunity

As long ago as 1887 Meierowitsch (1888) noted that rabbits which had recovered from a local infection were not susceptible to a subsequent general infection confirmed by many later workers, and Gromakowsky (1899) noted that

killed by freezing. Hence ice always contains but a fraction of the number in the water from which it was formed. Over 90 per cent both of the ordinary water bacteria and of typhoid bacilli die within a few hours, and a progressive decline in numbers then takes place, less than 1 per cent of typhoid bacilli surviving at the end of a week of freezing. Ice stored for six months is practically sterile. Outbreaks of typhoid fever have rarely been traced to the use of ice, although in a few instances the evidence of ice transmission seems quite conclusive. Danger of typhoid infection from the use of ice in drinking water is, in the absence of direct contamination of the ice during handling, always less than from the use of water from the same source as the ice.

The Bacteriological Analysis of Water.¹⁰ It will be apparent from the above discussion that the bacteria whose presence in water is a consequence of fecal pollution are not present in uncontaminated water and are sufficiently different from the native water bacteria that they may be readily distinguished. Of these bacteria *Bacterium coli* is present in greatest numbers, while *Streptococcus fecalis* and *Clostridium welchii*, although constantly present, are usually not so numerous. It would appear, therefore, that any of these microorganisms could be used as an indicator of pollution. Of these *Bact. coli* is the most satisfactory, although both *Str. fecalis* and *Cl. welchii* have been used in Europe. The streptococci are, however, sometimes difficult to differentiate and die out more rapidly than coliform bacteria. *Cl. welchii* has the disadvantage that its spores remain viable over long periods of time in contrast to *Bact. coli* which, although more hardy than the typhoid bacillus, dies out in time, hence *Cl. welchii* does not allow the differentiation of recent and old pollution. The quantitative relations between the coliform bacteria and the enteric pathogens are discussed at some length by Kehr and Butterfield.¹¹

The bacteriological examination of water for the presence of *Bact. coli* rests upon the fact that this microorganism ferments lactose. The standard procedure for the examination has been prepared jointly by the American Public Health Association and the American Water Works Association, and is revised at frequent intervals.¹² Briefly, it consists of three parts, (1) the presumptive test, (2) the confirmed test and (3) the completed test. In the first, lactose broth is inoculated with decimal dilutions of the water sample, commonly 10 ml., 1 ml. and 0.1 ml. (expressed as dilutions these are, respectively, 0.1, 1 and 10). The volume of the smallest inoculum producing fermentation provides a crude approximation of the numbers of *Bact. coli* present in the water. Of the selective enrichment media, containing ox bile and/or brilliant green or ricinoleate or lauryl sulfate, only lauryl sulfate tryptose broth has been officially accepted for the presumptive test without confirmation, and then not for filtered or treated waters. A more accurate estimate may be obtained by inoculating five tubes with each dilution and calculating the most probable number of *Bact. coli* on the basis of the number of tubes in which

¹⁰For British practice, which differs slightly from American, see Ministry of Health Rept. No. 71, *The Bacteriological Examination of Water Supplies*. His Majesty's Stationery Office, London, 1939.

¹¹Kehr and Butterfield. Pub. Health Rep., 1943, 58-589.

¹²This procedure may be found in detail in *Standard Methods of Water Analysis*, American Public Health Association, 9th ed., 1946, and in condensed form in most of the standard laboratory manuals.

We need not doubt that a local immunity exists, in the sense that one area of the tissues is more resistant than another to the consequences of a primary lodgment of a living bacterium or virus. The problem at issue is whether these *localized* differences in resistance can be accounted for by local variations in the effectiveness of the mechanisms we have considered in previous chapters, or whether some essentially different mechanism is operative.

Is the distribution of a local immunity confined to a particular type of cell or tissue, affecting that type of cell or tissue wherever it occurs in the body, or is this distribution determined by the site of inoculation, affecting all cells or tissues in the immediate neighbourhood of that site?

Continuing with the example of erysipelas, we may inquire whether it is the skin, as such and apart from other tissues, that is rendered resistant by the intracutaneous injection of living hæmolytic streptococci, or whether the effect is limited to the area of the initial erysipelatous reaction, affecting in that area all the cells or tissues involved in the inflammatory process.

The evidence is somewhat conflicting. The observations of Gay and Rhodes are consistent with the immunization of the skin as a whole, as the result of a localized experimental erysipelas. The findings of most other workers suggest that the distribution of resistance is, in the first instance, confined to the area affected by the erysipelatous reaction, though other areas of skin share in the more general immunity that may be induced by repeated injections of streptococci. As Amoss and Bliss showed, outside the area of erysipelatous reaction, the skin showing the greatest increase in immunity was that lying in the path of drainage through the underlying lymphatic plexus. The point is of some importance in deciding whether the increased immunity displayed by the skin as a whole results from immunization of the skin as an organ, or is only a manifestation of a high general immunity.

Landsteiner and Chase (1939) recorded some experiments which are relevant to the issue. They were able to sensitize the entire skin of a guinea-pig to poison ivy by local application of an extract to one area of it. Isolation of the area of application, by removing an annular piece of skin so as to leave an island, did not impair general sensitization even though the whole thickness of the skin was thus removed. When the underlying lymphatic plexus, and consequently the only pathway for the ready absorption of the extract into the body as a whole was severed, general sensitization did not follow application of the extract.

The question posed leads naturally to the one that follows it, and we shall consider the evidence relevant to its solution under this and other heads

Does the local immunity as such, and apart from an associated humoral immunity, confer an increased resistance on the body as a whole?

It will be convenient to commence our discussion of this question by setting out, in their baldest terms, the views that were put forward by Besredka (1919, 1920, 1921)

He noted that many, if not all, pathogenic bacteria tend to localize in particular tissues of the body. Thus the typhoid, paratyphoid and dysentery bacilli cause intestinal infection, and the anthrax bacillus commonly causes infection of the skin. However,

fermentation occurs. Tables for the calculation of the most probable numbers are given by Prescott, Winslow and McCrady.² The *confirmed test* consists of the inoculation of a specified selective medium such as Endo or eosin-methylene blue (EMB) plates, brilliant green lactose bile broth, crystal violet lactose broth, fuchsin lactose broth or formate ricinoleate broth. The appearance of typical *coli* colonies on the plates or fermentation in the selective lactose broth constitutes a positive confirmed test. In the *completed test* one or more typical colonies are picked from an Endo or EMB plate inoculated either from the original lactose broth culture or from the secondary selective medium showing fermentation and are transferred to an agar slant and a lactose fermentation tube. After incubation the slant culture is smeared and stained and examined for the gram-negative non-spore-forming rods of *Bact. coli*. If the culture is found to be morphologically *Bact. coli* and the lactose is fermented, the completed test is positive.

The Coliform Bacteria. Although *Bact. coli* is readily distinguished from the native water bacteria, the closely related *Bacterium aerogenes* is found in grains and elsewhere in nature though not, it may be noted, in virgin soils. The two bacterial species may be differentiated by a number of tests (p. 422), but these are not a part of the standard method of water examination; hence the gram-negative, lactose-fermenting bacteria whose presence is determined are more properly termed *coliform bacteria* rather than *Bact. coli*.

The Sanitary Significance of Coliform Bacteria. In recent years there has been a tendency in sanitary water analysis to emphasize the distinction between *Bact. coli* and *Bact. aerogenes*, the presence of the latter being considered by many to have little or no sanitary significance. There is no doubt that *Bact. coli* is more predominantly of "fecal origin" while *Bact. aerogenes* is found in greater relative abundance in soil than in sewage. For this reason it is maintained that a predominance of *Bact. aerogenes* over *Bact. coli* in a water supply is more indicative of soil contamination (the *coli* presumably of animal origin) or past pollution than of recent pollution. In general, however, while the proportion of *Bact. coli* to *Bact. aerogenes* is frequently correlated with the sanitary survey, there are too many exceptions to warrant attaching great significance to it. The ecology and significance of the different types of coliform bacteria found in water are reviewed and considered in detail by Taylor.¹³

It should be remembered, however, that coliform bacteria of all kinds are practically absent from virgin soils and from pure spring and surface waters, and that while *Bact. aerogenes* and intermediate forms are not present in feces in as great numbers as *Bact. coli*, their presence may nevertheless be demonstrated by appropriate methods.¹⁴ Even if it is true that *Bact. aerogenes* is somewhat more resistant than *Bact. coli*, and hence may survive in soil or water long after the latter has disappeared, the fact that its presence is not reliable evidence of *recent* pollution may not be as decisive as sometimes assumed. Experience in water examination has shown that it is not safe to disregard the warning of potential danger conveyed by evidence of soil washings and "past pollutions." It is unwise, therefore, in routine water analysis, to place

¹³ Taylor Jour. Hyg., 1942, 42:23.

¹⁴ Gray Jour. Hyg., 1932, 32:132; Bardsley: Jour. Hyg., 1934, 34:38

concluded that the rabbit can resist a large subcutaneous inoculation of *B. anthracis*, provided that the bacilli do not come into contact with any wound of the skin.

Other investigators have, however, recorded quite different results. Sobernheim and Murata (1924) estimated the minimal lethal dose of a culture of *B. anthracis* when administered by different routes. They found that about 1/10,000 of a loopful would produce death when introduced intraperitoneally or intravenously, about 1/100,000 of a loopful when introduced subcutaneously or intracutaneously and about 1/1,000,000 of a loopful when injected intramuscularly.

It is obviously difficult to avoid infecting the skin when making injections into any subjacent tissue, and this objection has been urged against those who have recorded successful infection by some route other than the intracutaneous; but Besredka's assumption can hardly be reconciled with the observation that a smaller dose of bacilli is required to produce a fatal infection when the inoculation is made into the muscles than when it is made directly into the skin. Similarly, Basset (1925) was unable to demonstrate any superiority of the intracutaneous as compared with the subcutaneous or intramuscular route. (See also p. 1185.) Müller's (1925) results are opposed to those of Plotz. Finding that anthrax bacilli would grow slowly through the pores of an L_1 candle, he placed cultures of the organism in such candles, sealed them carefully, and introduced them into the peritoneal cavities of nine rabbits. Seven of these animals died after intervals varying from 6 to 51 days. This long incubation period would appear to preclude an infection of the skin occurring at the time of the introduction of the candles. Burke and Barnes (1931) exploited the bactericidal action of gentian violet in an attempt to produce an initial subcutaneous infection with *B. anthracis* unassociated with any primary infection of the skin. A guinea-pig was injected with a young culture of *B. anthracis* by introducing the needle through the skin of the abdominal wall in one flank, and then passing it subcutaneously across the abdomen to the other flank, where the inoculum was deposited. The point of the needle was then withdrawn to just beneath the skin puncture, the syringe barrel was detached, another barrel containing a 1 per cent. solution of gentian violet was attached, and the dye was introduced into the puncture as the needle was withdrawn. The guinea-pig died in 56 to 72 hours. The characteristic gelatinous infiltration occurred at the point where the inoculum had been deposited, not at the point where the needle had been inserted. Cultures from the dye-stained area about the site of the skin puncture remained sterile.

Clearly Besredka's contention with regard to the unique susceptibility of the skin to anthrax has not been proved. Besredka and his colleagues (Besredka 1924*a, b*, Besredka and Urbain 1924) also attempted to immunize the skin against other bacteria. They applied filtrates from broth cultures of staphylococci or streptococci to the shaved skin of rabbits, and tested the resistance of these areas of skin to subsequent infection with the homologous organisms. They concluded that this procedure conferred a high degree of local immunity. In later reports they, and others, recorded valuable curative properties in these filtered cultures—the so-called "antivirus" preparations—but these observations do not bear directly on the problem at issue, and need not be further considered here.

We need not doubt that various procedures of this kind may raise the resistance of local areas of skin to subsequent infection; but it by no means follows that this is associated with an increase in the resistance of the body as a whole.

Thus, Hach, Borodaj and Melnyk (1928) state that staphylococci, after intravenous inoculation into rabbits, tend first (3-3½ hours) to accumulate in the spleen, few remaining in the blood and few being present in the skin. As the infection progresses towards its rapidly fatal issue the distribution changes; the number of cocci in the spleen rapidly diminish, the number present in the skin show an enormous increase. Multiple intradermal inoculations of a staphylococcal filtrate, preceding the intravenous injection, prevented this rapid accumulation of staphylococci in the skin (Hach and Melnyk 1928); but there was no effective immunity, the rabbits dying of typical acute staphylococcal infection.

too much stress upon the differentiation between *Bact. aerogenes* and *Bact. coli*, at all events until the practical value of such differentiation can be clearly demonstrated.

Plate Counts. It is usually desirable to have an approximate measure of the total number of bacteria in drinking water, not because the sanitary quality of a water can be judged on this basis alone, but because such information frequently has ancillary value. The counts obtained by quantitative dilution and plating are, it must be remembered, those of the microorganisms that will grow on the medium used, other bacteria being quite inapparent by this method.

Two series of plates are poured, one in which the medium is nutrient gelatin and the other nutrient agar, or both may be nutrient agar. The gelatin plates, or one set of agar plates, are incubated at 20° C. and the agar plates at 37° C.¹² In general the native water and soil bacteria grow best at 20° C.; in some cases they do not grow at all at 37° C.; and bacteria of animal origin grow most rapidly at body temperature. The relative numbers of microorganisms growing at the two temperatures are, then, at times suggestive of the origin of the bacteria found.

Chemical Analysis. The analysis for appropriate chemical compounds frequently is of value as an adjunct to bacteriological analysis in the determination of the sanitary quality of a water.¹² Pollution by sewage, for example, adds complex compounds, protein, carbohydrate and fat, to the water, and the amount and state of the decomposition products of these substances may serve as an index of the degree and time of pollution. Ammonia, nitrites, nitrates, chlorides and albuminoid nitrogen are usually determined. Of these, chloride, and to a certain extent nitrate, are the most useful. It may be noted that the chemical analysis of water is frequently made in connection with hardness, turbidity, taste, smell and similar features, which, while often of considerable industrial or esthetic significance, are of no sanitary importance.

The Assay of the Sanitary Quality of Water.¹³ The means by which the sanitary quality of a water is judged may be summarized briefly

- (1) The bacteriological analysis, including both
 - (a) the presence or absence of coliform bacteria and
 - (b) the number and type of bacteria present,
- (2) the type of water, whether surface or deep,
- (3) the local conditions, and
- (4) chemical analysis.

Of these the presence and numbers of coliform bacteria are the most important, and it must be remembered that the relative abundance, rather than the presence, of these microorganisms is the essential feature of the test. The discovery of a single colon bacillus in 50 ml. of water, or even occasionally in 5 ml., affords no reasonable ground for suspicion of the water. The possibility of sporadic contamination with colon bacilli derived not from man but from domestic animals or birds must be kept in mind. Manured fields and pastures, filled with grazing cattle or sheep, are likely sources of colon bacilli and may give rise to mistaken inferences if the environmental examination of a water supply is

¹³ Streeter: *Laboratory Control of Water Supplies* Public Health Reports, Suppl. No 201, 1948

Gay and Morrison (1923) injected various substances intraperitoneally into rabbits, and injected living streptococci 24 hours later. They found that certain substances, such as meat-extract broth, afforded considerable protection, whereas others, such as aleuronat, did not. They noted that the substances conferring protection were those that produced exudates in which macrophages were particularly numerous; on the other hand those that produced exudates containing numerous polymorphonuclear cells but few macrophages were far less effective.

Oerskov and Kauffmann (1936) and Oerskov (1940) recorded examples in mice of an intraperitoneal immunity to Vi forms of *Salm. typhi* and to *Sh. dysenteriae* that could be induced non-specifically by the injection of living or dead preparations of bacteria having no antigenic relationship to the infecting strain. Philipson (1937) made an extensive study of the immunity to *Sh. dysenteriae* induced in mice by vaccines of *Salm. paratyphi B*. A relatively high degree of non-specific immunity to intraperitoneal *Sh. dysenteriae* was demonstrable 8 hours after an intraperitoneal dose of vaccine, and lasted for 3-9 days. When two doses of vaccine were given at 9 days' interval, the immunity was demonstrable 2 hours after the second dose, and lasted up to 21 days. Thus the period of induction of the immunity was shortened, and its duration lengthened, by the re-vaccination. An intraperitoneal immunity of this degree, demonstrable 2 hours after the second dose of vaccine, could not be induced by intravenous vaccination and re-vaccination, nor by intravenous vaccination and intraperitoneal re-vaccination. Some immunity, however, followed intraperitoneal vaccination and intravenous re-vaccination, indicating that the stimulating effect of re-vaccination could be elicited in the peritoneum by blood-borne vaccine. Though the immunity was clearly non-specific, the stimulating effect of re-vaccination was in some way dependent on specific factors, for vaccination by one species of bacterium, and re-vaccination by an antigenically unrelated bacterium, was not followed by any significant increase in immunity.

Walsh and Cannon (1936) immunized rabbits against intranasal infection of the lungs with Type I pneumococci, by five or more daily instillations of formol-killed Type I pneumococci. The immunity was specific, though it appeared before antibodies were demonstrable in the blood of the animals. Cannon and Walsh (1937) recorded experiments which point to the induction of a local, perhaps specific, immunity in the lung by this procedure—an immunity apparently dependent on an increased resistance to the passage of the cocci from the alveoli into the tissues (see also Exchaquet 1936). Similar results were obtained by North and Anderson (1942), who found that intranasal *H. pertussis* vaccines were more effective than intraperitoneal vaccines for immunizing against intranasal *H. pertussis*. They concluded, however, that the superiority of the intranasal route was due to non-specific immunity, since the antibody response to vaccination by either route was similar. Intranasal vaccines made of organisms more or less related to *H. pertussis*—*H. influenza*, *H. parapertussis* and *H. bronchisepticus*—were also effective. No immunity resulted from instillation of staphylococci or pneumococci, but a *Bact. coli* vaccine was highly effective. The efficacy of the *Bact. coli* appeared to depend on its capacity to induce a histological reaction in the lung similar to that induced by *H. pertussis*. Serologically speaking, the effect was non-specific. It is salutary to reflect that, had the test with *Bact. coli* been omitted, the evidence would have been of the kind we are accustomed to regard as a reasonable indication of the specificity of a particular immunizing effect (see also Gray 1947, Cooper 1952).

Pullinger (1936, 1938) provided an instructive example of a clear-cut increase in non-specific local immunity dependent on the mobilization of cells in the lymph nodes of the guinea-pig. The generalized infection following an intramuscular injection of *Br. abortus* was largely inhibited when the organisms were injected together with a second bacterium, *Myco. tuberculosis* or *Listeria monocytogenes*. Injection of the second bacterium into another site did not affect the brucella infection, except to a very slight extent in animals receiving the tubercle bacillus; nor did the second bacterium act as an adjuvant, improving the animal's antibody response to the brucella. The effective immunization appeared

neglected. Knowledge of such local conditions as well as the type of water is, then, essential to the interpretation of the bacteriological findings. Chemical analysis may be of considerable help in some instances, but in general finds its greatest utility in the study and control of gross pollution in which the decomposition of organic matter and presence of industrial wastes are a nuisance, rather than the assay of the purely sanitary quality of a water.

Drinking Waters. The question of the significance of the bacteriological findings brings up the matter of standards to which a water suitable for drinking should conform. Now it will be clear that, although considerable numbers of colon bacilli in a water are always suggestive of fecal contamination by man or animals, a standard is necessarily a minimum which is inherently difficult to define under the circumstances. In this country the United States Public Health Service has prepared recommended standards¹⁶ which are intended to represent a minimum. In the recommended procedure the frequency of sampling is dependent upon local conditions, the minimum varying from one per month for a population of 2500, to 500 per month for a population of 5 million. The sample is 5 10 ml. portions, or 5 100 ml. portions. The results of bacteriological examination by Standard Methods procedures should be as follows

- (1) Of all 10 ml. portions examined per month, not more than 10 per cent shall show the presence of coliform bacteria.
- (2) Occasionally more than 3 of the 5 samples show coliforms, this must not occur in more than 5 per cent of samples when 20 or more samples are taken per month, or in more than 1 sample if less than 20 samples are taken per month.
- (3) Should such a result (as in 2) be obtained from a single standard sample, daily testing must be carried out until at least 2 consecutive satisfactory samples have been found. Such daily samples are to be regarded as "special samples" and not included in the monthly totals.
- (4) With regard to the 100 ml. samples:
 - (a) Not more than 60 per cent shall show coliforms.
 - (b) Occasionally all 5 portions constituting a single sample will show coliforms, this must not occur in more than 20 per cent of samples when 5 or more samples are examined per month, or in more than 1 if less than 5 samples are taken per month. If so, daily "special samples" must be taken as above.

The water shall be satisfactory as to taste, odor and color and shall contain less than the following chemical impurities: lead, 0.1 ppm, fluorine, 1.5 ppm, copper, 0.3 ppm, iron and manganese, 0.3 ppm; magnesium, chloride and sulfate, 250 ppm, total solids, 500 ppm phenol, 0.001 ppm.

The British Ministry of Health suggests standards¹⁷ based on the presumptive coliform count as determined by acid and gas formation in MacConkey broth on the piped supply entering the distribution system. Waters are divided into classes on the following basis.

Class I—Water of class I and regarded as highly satisfactory contains less than 1 coliform per 100 ml.

¹⁶ United States Public Health Service: *Manual of Recommended Water Sanitation Practice*. Pub. Health Bull. No. 296, 1946. These standards are also summarized in *Pub. Health Rep.*, 1946, 61:371; and in *Jour. Amer. Water Works Assn.*, 1946, 38 361.

¹⁷ *The Bacteriological Examination of Water Supplies*. Ministry of Health Series No. 71. His Majesty's Stationery Office, London. 1939.

acquire a specifically altered reactivity in this way. Work on the transference of the delayed type of hypersensitivity provides an example of an even more profound specific modification of cells, in this case the lymphocytes. These examples of specific immunological changes relate to hypersensitiveness; in the field of immunity proper, we have Lurie's demonstration (p. 1197) of an acquired apparently *cellular* immunity to the tubercle bacillus as a model for the kind of property we are discussing.

Little is known about non-specific immunity at the cellular level. As we saw in Chapter 53, the distribution of infective lesions among the various organs of the tuberculous animal suggests an organ resistance which may be referable to some antibacterial substance peculiar to, or in abundance in, the cells of that organ. Equally characteristic, though different, distributions occur in other bacteræmic infections, as reference to various bacterial pathogens in Parts II and IV will show.

The freedom of a given organ from lesions due to blood-borne infection can, however, be no more than suggestive of an organ immunity based on peculiarities of the cells of that organ, until alternative determining factors, like the anatomical relations of the organ to the blood stream, are eliminated.

SUMMARY

The evidence available appears to justify the following conclusions.

(1) By the injection of various materials into the tissues, and by certain analogous procedures, it is possible to induce an immunity which is confined to the neighbourhood of the treated area, and is not shared by the body as a whole.

(2) This immunity appears to be distributed in accordance with the area involved in the original inflammatory reaction, *not in accordance with the distribution throughout the affected part or throughout the body generally of one particular type of cell.* There is good evidence of a localized immunity affecting a *region* of skin, or a particular serous sac. There is no adequate evidence of an immunity affecting the skin as a whole, or the intestinal mucosa as a whole, or serous surfaces as a whole, except as the expression of a general immunity.

(3) It follows that we cannot accept the conclusion that a localized immunity of the latter type is an essential factor in a general immunity. Even had an induced skin immunity, or mucous membrane immunity, been shown to exist, our knowledge of the general defence mechanisms of the body would prevent us from regarding such a local increase in resistance as the essential factor in antibacterial immunity.

(4) All the evidence suggests that non-specific factors are of primary importance in those instances of local immunity that have been submitted to experimental study. It would appear to be the initial inflammatory reaction as such, and the cellular changes which persist for some time after it has subsided, that determine the relative resistance of the treated area to subsequent experimental infections. In particular it would seem that any treatment which induces a local mobilization and concentration of histiocytes will confer on the treated area an increased resistance, which will last as long as the local cellular changes persist. There is some evidence that with the decline of the cellular change, the treated area remains for some time more responsive than normal to non-specific immunization.

A
class I, not more than 80 per cent below class II, and none below class III.

While a presumptive test alone is specified, the occurrence of positive presumptive tests has been found to be very high in Britain. Waters of classes I and II conform closely to the American standards.

Swimming Pools and Bathing Places. The sanitary control of water in swimming pools and bathing beaches is similarly based on bacteriological examination. The American Public Health Association has recommended that not more than 15 per cent of samples of swimming pool water contain more than 200 bacteria per ml. or give positive confirmed tests for coliforms in any of 5-10 ml. samples when the pool is in use. The standard is as high as that for drinking water, but pools are usually filled with water of drinking quality and pollution is not only derived from bathers but is fresh and may be highly infective. The presence of acid forming streptococci is also of considerable utility as a measure of oral and skin contamination, and usually corresponds closely to the total count. Such waters commonly contain residual chlorine which must be neutralized with thiosulfate when samples are collected for bacteriological examination. In natural outdoor bathing places the test for coliforms is the most important. The standards are necessarily much more lenient than those for indoor pools, and those adopted locally vary from an allowable 100 coliforms per 100 ml. in California and Indiana to 3000 coliforms per 100 ml. allowed by the New York City Health Department.

The Purification of Water Supplies. When, by bacteriological examination or otherwise, a water is known to be unsafe for consumption, the question arises as to ways and means of artificial purification. There are a number of useful methods of purifying water, differing according to the amount and character of the water to be treated, which may be summarized as follows:

(1) mechanical methods

(a) storage

(b) filtration

1. slow sand filtration

2. coagulation and rapid sand filtration

(2) chemical methods

Of these methods, storage and slow sand filtration are the simplest and most economical. They are, however, not always applicable. In some cases, particularly in the purification of impounded waters because of the exhaustion of the food supply and the consequent death of bacteria and settling, not so much of bacteria alone as of suspended matter which carries down bacteria with it. The partial removal of suspended matter is frequently desirable, particularly with turbid waters, and may be carried out by allowing the water to remain in a settling basin for a time.

Slow sand filtration is one of the earliest and most effective methods of water purification and is in use in many European and some of the older American

CHAPTER 54

THE INFLUENCE OF DIET, FATIGUE, CHANGES IN TEMPERATURE AND HUMIDITY, CHEMICAL AND CHEMOTHERAPEUTIC AGENTS AND OTHER FACTORS ON GENERAL OR LOCAL IMMUNITY

The Influence of Diet on Immunity

THE traditional association of famine and pestilence epitomizes an age-old belief in the influence of diet on resistance to infective disease. Modern epidemiology and social medicine have substantiated that belief by establishing associations between malnutrition and certain infective diseases—such as tuberculosis. Malnutrition itself, however, is in turn linked with so many interrelated and variable factors in the human environment, and the human herd is so ill-suited to the kind of controlled experiment that would enable us to estimate the importance of these other factors, that there are few instances where the association could with complete confidence be interpreted as a causal relation.

To establish that relation we have at present to rely almost entirely on animal experiment. Our success in the field will depend firstly on how far the defence mechanisms that are susceptible to investigation adequately represent the processes likely to be influenced by diet; and secondly on how far we can identify the effective components of the diet, and their relation to one another. We must consider the food as a source of energy, of nutrients, and of accessory food factors. We shall find many reports on the action of dietary factors to be contradictory; in some cases, doubtless because the components of the diets were heterogeneous, and in others because in each experiment different variables were controlled.

We discussed in Chapter 43 some of the variables that affect the measurement of resistance; for example, the genetic constitution, age, sex, and methods of maintenance of the experimental animals. The commonest dietary test consists in depriving the animal of a food; but such deprivation means little unless we know such things as the initial nutritional state of the animal, how long the deprivation should be maintained to ensure that the animal's tissue reserves of the food in question are depleted, and whether the food is not being supplied, say, by the microbial flora of the gut (see Chapter 49). When the animal is depleted, the observed changes in resistance may be due, not to the lack of one factor, but to the presence of another whose ill-effects in the full diet were antagonized by the factor we have removed. Again, the depletion may have caused a loss of appetite, and so led to an effective deficiency of a factor in the diet on which the animals are being maintained. These ambiguities can sometimes be avoided by proper design of the test. In the design, we must also decide what kind of resistance to measure. If, for example, we infect the animal by natural means—such as the oral route in mouse typhoid—the subsequent morbidity rates will measure resistance to infection; but if we use the intravenous route, we should be testing the capacity of the tissues to resist the consequences

cities. These sand filters are constructed so that the water passes through 1 to 5 feet of sand supported upon graded layers of gravel (see Fig. 33). The rate of filtration must be accurately regulated and the efficiency of operation controlled by frequent bacterial tests of the effluent. Such filters are highly effective. Bacteria are removed, not to any great extent by mechanical straining out, but through a biological mechanism in which the activity of protozoa is an important feature. The passage of water through these filters is necessarily a relatively slow process and, in consequence, relatively large areas are required, which, for financial or other reasons, are no longer available in large American cities. Few of these filters have been constructed in recent years, and the use of rapid sand filters is becoming common.

The rapid sand filters, which may be used with turbid waters that would clog a slow sand filter, are frequently employed in conjunction with "coagulation," the addition of such substances as aluminum or ferric sulfate, which form flocculent precipitates (the hydroxides). The precipitate carries down most of the suspended matter and, of course, many bacteria, and is readily filtered out,

Fig. 33. Cross-section of filter plant (after Hazen).

yielding a clear effluent containing relatively few bacteria. Laboratory experiments on centrifugation of dilute suspensions of *Bact. coli* in the presence of kaolin or infusorial earth have indicated that 70 per cent of the viable cells are found in the sediment.¹⁸ Such filters must be cleaned from time to time, a process that is seldom required with slow sand filters. They make possible, however, the treatment of a large quantity of water on a relatively small filtering area.

Destruction of pathogenic bacteria in water supplies is most often brought about by treatment with germicidal chemicals. Of these, hypochlorite (calcium hypochlorite or bleaching powder) was at one time used widely in the treatment of municipal water supplies, and it still has its uses, although it has been largely superseded in large scale treatment by liquid chlorine, which is supplied in cylinders under pressure. Chlorine is added directly to the water through an automatic feeding device in accurately measured amounts which are determined by the character of the water. In general, the greater the amount of extraneous organic matter present, the greater must be the amount of chlorine added. The amount of chlorine taken up is termed the chlorine demand, and the point at which the residual chlorine or available chlorine becomes proportional to the added chlorine is called the "breakpoint" in the chlorine demand curve. The introduction of breakpoint chlorination usually

¹⁸ Schulhoff and Hueckelkian: Jour. Amer. Water Works Assn., 1936, 28.1963.

significantly lower epidemic mortality occurred in the groups whose diets included the dried milk. The better diet apparently reduced the risk both of manifest, and of latent infection.

Church (1939) recorded results substantially in agreement with these using *Salm. enteritidis* as the infecting agent; the dietetic effects were far more readily produced in young mice when the mothers were also subjected to the diet from a few weeks prior to mating. Indeed, the only changes found to exert a significant effect when instituted first in the weaned mouse occurred as the result of a 75 per cent. decrease in the total mineral constituents or an 80 per cent. decrease in calcium content.

Reference to the protocols of Webster and Pritchett (1924), Pritchett (1927), and Topley, Greenwood and Wilson (1931) shows that Watson's results were entirely compatible with the view that the milk powder in the earlier diets was the component that determined the increased resistance of the mice receiving it, though this possibility was not at that time envisaged. It would appear that the tissue changes on which increased resistance depends take some time to develop. The mode of action of the milk powder is obscure. The reproduction of Watson's mice was poor on the high oatmeal diet. Howie (1949) observed that reproduction of mice was better on low oatmeal than on high oatmeal diets, and suggested that Watson's milk powder diet had raised resistance by adjusting an imbalance in her poor diet. This may well be so, though it should be noted that a diet good for reproduction and growth of an animal is not necessarily the best for resistance to a given infection. Howie and Porter (1950), for example, among six diets tested, found no constant association between growth and reproduction on the one hand, and resistance to salmonella and the tubercle bacillus on the other.

Sengupta and Howie (1949) recorded that of two diets, one richer than the other in calcium, protein and vitamins promoted the greater resistance of mice to tuberculosis initiated by intravenous injection of the bacilli.

Schneider (1946b, 1948, 1949) examined a diet of whole wheat and whole dried milk, which had proved better than a "synthetic" diet in promoting resistance to oral *Salm. enteritidis* in mice. The effective factor proved to be a thermostable constituent of wheat, corn, yeast and grass. His experiments illustrate the importance of the genetic constitution of the mice used, and the state of the infecting organisms, which had to be nicely adjusted to reveal significant differences in resistance; the best results were obtained with a heterogeneous population of mice, and a mixture of virulent and avirulent forms of the salmonella.

In experiments on sheep, which were carried out in Scotland, animals were allowed to graze on different types of pasture, or fed on different diets in pens, and studies were made of the blood calcium, blood phosphorus, and (as an index of immunity *faute de mieux*) of certain of the natural agglutinating or lytic antibodies. The results, as one would expect, were by no means easy to interpret; but there appeared to be a definite correlation between ample pasturage, a high calcium and low phosphorus content of the blood, and general well-being, and there was a suggestion that these conditions were associated with active lytic properties of the serum, while the agglutinins in certain experiments appear to have varied inversely as the lysins (Orr *et al.* 1931). In later experiments (Mackie *et al.* 1932) a slight indication was obtained that the animals on the poor pasture were more susceptible than controls to the intradermal injection of the toxin of the lamb dysentery bacillus.

Proteins.—As regards the proteins, we may first note that experimental depletion of the serum proteins in dogs, by repeated bleedings and replacement of whole blood by erythrocytes alone, or experimental hypoproteinæmia and anæmia together, is associated with a high incidence of endocarditis, pneumonia and septicæmia (Robschey-Robbins, Miller and Whipple 1943). Hypoproteinæmia of rats and rabbits induced by low protein diets is associated with increased susceptibility to Type I pneumococcal infection, and a decreased formation of antibody, as evidenced by a poor response to specific immunization

results in material improvement in the sanitary quality of a water.¹⁹ When liquid chlorine is added to ordinary surface water, clear and not highly contaminated, in the proportion of about 0.5 to 1 part of "available chlorine" per million gallons, the ordinary intestinal bacteria are destroyed, including such pathogenic forms as the typhoid bacillus.²⁰ The tastes and odors in chlorinated waters may be due to an overdose of chlorine caused by inadequate control methods, or to the action of chlorine upon compounds present in the water, commonly as industrial wastes. Excess chlorine and tastes caused by chlorination can often be removed by dechlorination with SO_2 or treatment with KMnO_4 or activated carbon. The bactericidal activity of chlorine may be prolonged, particularly in waters containing considerable organic matter, by the simultaneous addition of liquid ammonia with the formation of chloramines.²¹ The introduction of chlorination of municipal water supplies has, in practically every instance, resulted in marked reductions in the incidence of enteric infection, typhoid fever in particular, in this country. The addition of chlorine or other bactericidal agents is not a "cure-all" however. When a water is sufficiently heavily contaminated, bacteria embedded in particles of organic matter are not killed even in the presence of available chlorine. It is generally agreed that a content of more than 50 coliform bacteria per milliliter indicates pollution too great for successful chlorination.

In the last few years chlorine dioxide (ClO_2) has been applied to the treatment of water. It has the advantages that it destroys algal tastes as well as the chlorophenol taste of certain chlorinated waters, and oxidizes organic matter more rapidly than chlorine, thus allowing the maintenance of a chlorine residual in the distribution system. In water solution this substance is decomposed by light to chloric and perchloric acids and oxygen, and is more bactericidal for coliform bacteria than chlorine.²²

It may be noted that frequently a combination of filtration and chlorination is desirable particularly with rapid sand filters. Not only does a preliminary filtration have esthetically desirable features in the case of turbid waters, but considerably less chlorine is required for treatment than would have been the case had not the greater part of the suspended material been removed.

The chemical treatment of water on a small scale does not always involve expense as a primary consideration and hence other methods are not infrequently used. The treatment of swimming pool water by ultraviolet irradiation adds no tastes or odor to the water and, although considerably more expensive than chlorination, can be used because the scale of operation is small. Ozone, which is strongly bactericidal, is also relatively expensive and is not commonly used in this country but is used to an appreciable extent in Europe.²³ Chlorina-

²³ See the review on ozone treatment by Hann: *Jour. Amer. Water Works Assn.*, 1943, 35:585.

response, may obscure real differences in rates of synthesis, which might appear were the response to be tested at a lower level of efficiency. Thus, Howie, Barr and Glenn (1953) observed an increase in diphtheria antitoxin formation by ewes when a supplement was added to a grass diet, but only with the less efficient interval of 4 weeks between primary and secondary doses; when the interval between the stimuli was 9 weeks, the better response in both test and control animals masked this difference (see Balch 1950, above).

Minerals.—The possibility that variations in the intake of mineral salts might have an influence on resistance was explored by various experimental workers (Zilva 1919, Lange 1925, 1927*a, b*, Pritchett 1927, Hotta 1928, Kligler and Geiger 1928, Mayer and Sulzberger 1931, Sulzberger and Mayer 1931), but, excepting the results of Church (1939) noted above, the evidence is highly confusing.

Clark and his colleagues studied the effect of single mineral deficiencies in mice; variations in Ca, Mg and Cl had no effect on susceptibility to Theiler's encephalomyelitis virus; the incidence of paralysis, but not the death rate, was decreased by Na deficiency and by depletion of either K or P (Rasmussen *et al.* 1944, Lichstein *et al.* 1946). A rather different mineral effect was recorded by Hitchings, Falco and Sherwood (1949), who identified manganese as a dietary factor that in mice *enhanced* the infectivity of certain strains of pneumococci, apparently by supplying a growth factor to the organisms (see also p. 1387).

Apart altogether from their effect on the defence mechanisms of the tissues, there can be no question that variations in diet alter the local conditions in the gastro-intestinal tract. We know (see Rettger and Cheplin 1921, Dudgeon 1926) that the ingestion of certain foodstuffs produces characteristic changes in the gastro-intestinal flora; and Arnold (1926, 1927*a, b*, 1929) has stressed the importance of various food materials in deranging or maintaining the efficacy of the gastro-duodenal bactericidal mechanism, particularly in infants. He suggested that such results as those recorded by Webster and Pritchett (1924) and Pritchett (1927) might be due in part to effects of this kind.

We may note here an association between infection and hypersensitiveness to diet, which may prove to be of some importance in the study of resistance. Coca (1941) observed in man a syndrome that he ascribed to food allergy, and found that the incidence of the "common cold" was higher among allergic than among non-allergic human beings. Brown and others (1943) confirmed his observations.

Accessory Food Factors

The Fat-soluble Vitamins A and D.—In 1909 Knapp described in rats on a deficient diet the condition of xerophthalmia, which is characterized by a patchy thickening and drying of the epithelium of the eye, associated in its later stages with subacute bacterial infection of the underlying tissues. This condition later proved to be due to lack of the fat-soluble Vitamin A. It was found in other animals, such as the dog (Steenbock *et al.* 1921) and rabbit (Boock and Trevan 1922), and occurred in Danish children during the 1914-18 war (Bloch 1921, 1923). The bacterial infections are not limited to the eye. Bloch noted that the xerophthalmic children were unable to withstand infections of any sort, and died quickly of serious intercurrent fever. The most important killing disease was broncho-pneumonia. Blegvad (1923) recorded the following incidence of serious complicating infections among the cases of xerophthalmia—broncho-pneumonia 63, bronchitis 45, pyuria 42, otitis media 30. These clinical observations are in *entire* accord with the results obtained in dietary experiments on animals.

The liability of rats fed on a diet deficient in Vitamin A to develop intercurrent infections, such as glandular abscesses, suppurative arthritis, suppurative

tion is, of course, always available. It is carried out by the addition of hypochlorite when the installation of liquid chlorine apparatus is not desirable, as, for example, in the treatment of a contaminated cistern.

At times the treatment of water becomes an individual matter, as in the case of an army in the field or when a public supply is known to be impure. In the first instance the water may be treated by the addition of hypochlorite in the form of bleaching powder or a solution of sodium hypochlorite, or by the addition of a small amount of iodine, one part of Lugol's iodine solution to 1000 parts of water. In the home, filters, such as the Berkefeld or Chamberland bougies, may be used, but filtration is slow and care in operation and frequent cleaning are necessary. The simplest and best method of water treatment for the family or individual, however, is simple boiling. Boiling for five minutes is quite sufficient to destroy with certainty the typhoid bacillus and allied forms as well as the cholera vibrio. When water-borne disease is prevalent, or when a water supply is notoriously impure or exposed to chance of infection, boiling is the only wholly safe procedure.

SEWAGE

Sewage is best regarded as the used water supply of a community and as such is a dilute solution of fecal matter and other wastes. From the hygienic point of view it is an important vehicle in the transmission of enteric infection, hence the manner of its disposal is of considerable significance. The mechanisms of sewage disposal have as their objects first, the ridding of a community of an ever-present volume of waste and second, disposal in such a manner that it is not dangerous to other communities.

The complex organic compounds present in sewage undergo the same processes of decomposition that are involved in the breakdown of dead organic matter in nature and are a part of the so-called cycles of elements such as nitrogen, phosphorus and the like. Any type of sewage treatment, then, is nothing more than a mechanism for bringing about or accelerating these transformations. The organic compounds are first broken down to amino acids, monosaccharides and the like, which are eventually oxidized completely to carbon dioxide and water in the case of carbon and hydrogen, and to nitrite and nitrate in the case of nitrogen. Bacteria are the active agents in this decomposition and oxidation, the mechanisms of which have been discussed earlier (Chapter 4). Although essentially simple in principle, sewage treatment is in practice a complex problem which cannot be considered at length here.²⁴

In general, however, sewage disposal falls into one of three categories: (a) dilution, (b) partial treatment and (c) complete treatment. In the first instance the sewage is simply dumped into some body of water where it will not annoy its originators. Here the breakdown and oxidation of the constituents of the sewage occur in nature, and, if sufficient time elapses, no trace remains beyond an increase in nitrate which, in turn, serves as food material for phytoplankton. When this transformation takes place in a flowing stream, the phenomenon is known as the *self-purification of streams*. The essential element, however, is not the fact that the water is in movement but that sufficient time

²⁴ See Imhoff and Fair. *Sewage Treatment*. John Wiley & Sons, New York 1940.

rats suffered from spontaneously acquired infection, which may itself have affected the phagocytic index. The significance of lysozyme in defence against infection is not clear (see Chapter 45), but it may be noted that in deficient rabbits Sullivan and Manville (1937) found a retention of lysozyme in the intestinal tissues, and a diminution in the mucous secretions.

Observations have been recorded suggesting that the deprivation of Vitamin A renders animals more susceptible to the injection of bacterial toxins, as well as to the invasive action of living bacterial cells (Werkman, Baldwin and Nelson 1924, Schubert 1928). Torrance (1936), however, in a careful study of the Vitamin A content of the liver in guinea-pigs, found no association between vitamin level and susceptibility to diphtheria or tetanus toxin (see also Chalier and Jeune 1938).

It is possible that the whole effect of Vitamin A deficiency is indirect. Kligler, Guggenheim and Henig (1945) found, in accordance with a number of other observers, that resistance of rats and mice to infection—in their case with *Salm. typhi-murium*—was not significantly lowered by a partial Vitamin A deficiency, but only by a complete avitaminosis. Avitaminosis was, however, invariably associated with declining weight in the experimental animals. In other words, the decline in resistance appeared to be due to starvation, a conjecture supported by the fact that rats whose food intake was restricted to the same amount as that eaten by avitaminotic rats but whose Vitamin A intake was normal, were as susceptible as the avitaminotic animals to the salmonella infection.

We have been concerned so far with Vitamin A deficiency, which appears to be moderately disadvantageous to the animal. There is little evidence, either experimental or from the field, to determine whether excess of the vitamin is beneficial.

In mice orally infected with *Salm. typhi-murium*, Pritchett (1927) observed that withdrawal of butter-fat, as a source of Vitamin A, from the McCollum diet (p. 1367) containing wheat flour, casein, milk powder and salts decreased resistance; and its addition to a diet of bread soaked in milk, with supplements of oatmeal and buckwheat, increased the resistance.

But with contact infections during an experimental *Salm. typhi-murium* epidemic in mice, Topley, Greenwood and Wilson (1931) found that the addition of excess Vitamin A in the form of butter-fat, or a vitamin concentrate, or as provitamin A in carrots, to a basal diet of wheat flour, casein, butter and a salt mixture, slightly increased susceptibility, whereas these supplements did not affect the mortality of intraperitoneally infected mice.

These experiments have a bearing on the effect of an excess of Vitamin A over the amount required to maintain growth and well-being; but it would be unwise to lay much stress on their significance, since the diets employed varied in many ways besides their differences in Vitamin A content. We may conclude that no adequate experimental evidence has yet been produced to show that an excess of Vitamin A over the level required to prevent all overt signs of avitaminosis induces an increased resistance to bacterial infection.

Little evidence is available with regard to the effect of increasing the amount of Vitamin A supplied to human subjects. Antibody formation has not received much attention. Scaglione (1938) concluded from a study of rabbits and young children that Vitamin A improved the agglutinin response to T.A.B. vaccines; and Schmeckebier (1943) reported an increase of diphtheria antitoxin in the blood of women given Vitamins A and D. As regards resistance to infection itself, the bacterial complications of child-birth afford opportunities for such a trial, and are of particular interest because of the obvious possibility that pregnancy may make a large call on the vitamin reserves. Mellanby, Green and their colleagues (Green *et al.* 1931) recorded a trial in which 275 women received a Vitamin-A concentrate

elapses for the breakdown and oxidations to proceed to completion. Soil polluted with sewage similarly "purifies itself."

With increasing population densities the disposal of sewage by dilution becomes unsatisfactory because a body of water is not infrequently a water supply to a neighboring community. Some form of treatment, then, becomes obligatory, in other words, the decomposition is made to take place in whole or in part in the various tanks and other devices making up a sewage treatment plant rather than allowing it to occur in natural bodies of water. In practice, treatment takes the form of preparatory processes followed by a period of *anaerobic digestion*, then a period of *aerobic oxidation*. Treatment may be complete even through nitrification, or the partially treated sewage may be disposed of by dilution.

When the disposal of fecal material is an individual or family problem the mechanics involved are somewhat different, but the processes of decomposition and oxidation are essentially the same whether a privy, cesspool or septic tank is used.

It will be noted that, although sewage treatment is basically a bacteriological process, the pathogenic bacteria are not involved; their presence is not taken into consideration, nor is there any effort to destroy them except in the rare instances in which the effluent from a complete treatment plant is chlorinated. In one sense, then, sewage treatment is not directed toward the control of water-borne disease. The fact that it is treated, however, is of considerable significance in this connection. When sewage is disposed of by dilution, the typhoid bacillus and related microorganisms do not multiply; rather, a decline in numbers sets in immediately, and these bacteria do not survive as long in water as in soil, probably not more than a few days or a week. It is probable that they tend to disappear equally rapidly during sewage treatment, although

economic and esthetic aspects of sewage treatment are, of course, another matter.

Vitamin C (ascorbic acid). In the earlier records there are suggestions that B-avitaminosis is associated with a minor increase in susceptibility to infection, but the evidence is of very doubtful significance (see Werkman 1923a, b, Werkman, Baldwin and Nelson 1924, Lassen 1929, 1931, 1932, Robertson 1934).

The effect of a prolonged suboptimal intake of the vitamin B complex was studied in rats by Drummond and others (1938). The deficient rats had feebler reproductive powers, were shorter-lived, and *post mortem* showed a significantly higher incidence of gastro-intestinal lesions than those in a control group on a full diet. Nevertheless, they suffered from no epidemics, and the incidence of bronchiectasis, the only infective disease to which the rats were prone, and of sporadic pneumonia and abscesses, was the same in deficient and control groups. Rose and Rose (1936) compared the course of artificial *Staph. aureus* bacteraemia in 8 normal and 8 B₁-deficient dogs. The deficient dogs lost weight more rapidly, and suffered a more prolonged bacteraemia, but there was no significant difference in the recovery rates in the two groups. They found no depression of resistance to *Cl. welchii* toxin in deficient dogs (Rose, Rose and Kolmer 1936). Janota and Dack (1939) record that the anaemia, leucopenia, gingivitis, oedema and diarrhoea which follow B₂ deficiency in monkeys is associated with the spontaneous appearance of *Sh. flexneri* in the stools. Rats fed on B-deficient (Lamb 1935) or thiamin-deficient diets (Badger, Masunaga and Wolf 1940) exhibit a decreased resistance to rat leprosy. Wooley and Sebrell (1942) maintained mice on thiamin- and riboflavin-deficient diets for 2-3 weeks, and found a diminished resistance to intranasal infection with Type I pneumococci. Day and McClung (1945) observed a slight diminution of resistance to intraperitoneal infection with pneumococci in pantothenate-deficient mice, but not in similarly treated rats. Robinson and Siegel (1944), using comparatively small numbers of animals, studied the effect of restricted B vitamin intake on rats injected intratracheally with a mixture of mucin and Type I pneumococci. Compared with rats on a defined "synthetic" diet containing adequate amounts of known B vitamins, neither riboflavin- nor pantothenic acid-deficient rats were less resistant; thiamin deficiency, and to a less significant degree, pyridoxine deficiency, lowered the resistance. Rats on a "normal" stock diet, it should be noted, were as susceptible as thiamin-deficient rats.

Guggenheim and Buechler (1946) found in mice a decreased resistance to oral infections by *Salmonella typhi-murium* that was attributable to thiamin deficiency. In their thiamin-deficient rats, however, the decrease they observed was due to the accompanying inanition due to poor caloric intake. Inanition, rather than vitamin deficiency, appeared also to be the cause of increased susceptibility to relapsing fever spirochaetes in thiamin-deficient rats (Guggenheim and Buechler 1946). Folic acid deficiency in monkeys, carried to the point where the animals were leucopenic, was reported greatly to decrease resistance to infection with influenza virus and with streptococci initiated by the nasal route (Saslaw *et al.* 1946).

The severity of rickettsial infections of the rat and the guinea-pig are increased on a starvation diet (Zinsser *et al.* 1931.) Vitamin-A deficiency does not depress the resistance of the rat to murine typhus, but riboflavin deficiency does so strikingly; and repair of the deficiency, even in the late stages of a fatal infection, is curative (Pinkerton and Bessey 1939).

Number of B vitamin deficiencies in rats, Fitzpatrick (1948) found that only

Amongst the B vitamins, only B₁ and B₂ deficiencies were found to have a marked effect on resistance to infection. Kuczynski (1937) increased the survival rate of normal mice injected with yellow fever virus from about 20 per cent. to about 75 per cent. by increasing the dietary thiamin. It is doubtful whether these effects are specific. For example, Sabin (1941) has shown that though thiamin or B-complex deficiency delays the normal acquisition by mice of

tion is, of course, always available. It is carried out by the addition of hypochlorite when the installation of liquid chlorine apparatus is not desirable, as, for example, in the treatment of a contaminated cistern.

At times the treatment of water becomes an individual matter, as in the case of an army in the field or when a public supply is known to be impure. In the first instance the water may be treated by the addition of hypochlorite in the form of bleaching powder or a solution of sodium hypochlorite, or by the addition of a small amount of iodine, one part of Lugol's iodine solution to 1000 parts of water. In the home, filters, such as the Berkefeld or Chamberland bougies, may be used, but filtration is slow and care in operation and frequent cleaning are necessary. The simplest and best method of water treatment for the family or individual, however, is simple boiling. Boiling for five minutes is quite sufficient to destroy with certainty the typhoid bacillus and allied forms as well as the cholera vibrio. When water-borne disease is prevalent, or when a water supply is notoriously impure or exposed to chance of infection, boiling is the only wholly safe procedure.

SEWAGE

Sewage is best regarded as the used water supply of a community and as such is a dilute solution of fecal matter and other wastes. From the hygienic point of view it is an important vehicle in the transmission of enteric infection; hence the manner of its disposal is of considerable significance. The mechanisms of sewage disposal have as their objects first, the ridding of a community of an ever-present volume of waste and second, disposal in such a manner that it is not dangerous to other communities.

The complex organic compounds present in sewage undergo the same processes of decomposition that are involved in the breakdown of dead organic matter in nature and are a part of the so-called cycles of elements such as nitrogen, phosphorus and the like. Any type of sewage treatment, then, is nothing more than a mechanism for bringing about or accelerating these transformations. The organic compounds are first broken down to amino acids, monosaccharides and the like, which are eventually oxidized completely to carbon dioxide and water in the case of carbon and hydrogen, and to nitrite and nitrate in the case of nitrogen. Bacteria are the active agents in this decomposition and oxidation, the mechanisms of which have been discussed earlier (Chapter 4). Although essentially simple in principle, sewage treatment is in practice a complex problem which cannot be considered at length here.²⁴

In general, however, sewage disposal falls into one of three categories: (a) dilution, (b) partial treatment and (c) complete treatment. In the first instance the sewage is simply dumped into some body of water where it will not annoy its originators. Here the breakdown and oxidation of the constituents of the sewage occur in nature, and, if sufficient time elapses, no trace remains beyond an increase in nitrate which, in turn, serves as food material for phytoplankton. When this transformation takes place in a flowing stream, the phenomenon is known as the *self-purification of streams*. The essential element, however, is not the fact that the water is in movement but that sufficient time

receiving adequate Vitamin C and of those on a vitamin-deficient diet. Vogl (1937) reported that Vitamin C prevented the development of post-operative pneumonia, and that it hastened the convalescence of pneumonic patients (see also Scnewald 1938, Szirmai 1940). Beneficial results have been claimed also in the treatment of whooping cough (Ormerod and Unkauf 1937), though Gairdner (1938) in a carefully controlled test found no difference between untreated and vitamin-treated children. Bamberger and Zell (1936), Dieckhoff and Schüler (1938) and Szirmai (1940) also claimed beneficial results in diphtheria. In most cases, however, the number of uncontrolled factors in these tests was large, and conclusions as to the specific action of the vitamin must be drawn with circumspection.

Glazebrook and Thomson (1942) provided one of the most clear-cut indications of a specific Vitamin C effect. They studied two groups of boys, one deficient in, the other saturated with, Vitamin C. They could find no difference in the incidence of common colds or tonsillitis in the two groups, but noted that deficient patients with tonsillitis stayed in hospital 16.7 days on the average, as against 10.0 days for the saturated patients. During the period of observation there were 17 cases of pneumonia and 16 cases of acute rheumatic fever among 1,100 deficient boys, and none among 335 saturated. The association of infection with low vitamin levels in animals or man is not in itself good evidence that the one is a direct result of the other, for in the infective state, especially when it is accompanied by fever, there is a decrease of the vitamin in the tissues; indeed, infection may precipitate scurvy in persons suffering from hypovitaminosis (see Abbasy *et al.* 1937*a, b*, Harris *et al.* 1937, Fox 1943). The point is well illustrated in the attempts of Rinehart and his colleagues to reproduce the lesions of rheumatic fever in guinea-pigs. They found (1934) that infection of scorbutic guinea-pigs with hemolytic streptococci resulted in certain cardiac lesions which did not appear in scorbutic animals, or in normal animals infected with the streptococci. Moreover, in patients with rheumatic fever, the vitamin levels were unusually low (1936). McBroom and his colleagues (1937), on the other hand, observed the lesions in uninfected scorbutic guinea-pigs, provided that the scurvy was severe enough, and suggested that Rinehart's lesions were due to severe scurvy, precipitated in a non-specific manner by the superadded infection.

As regards spontaneous infections in guinea-pigs suffering from experimental scurvy, Hamburger and Goldschmidt (1922-23), Grant (1926, 1930) and Schmidt-Weyland and Koltzsch (1927) state that they are very common. On the other hand, Holst and Frölich

as relevant evidence, though we clearly cannot assume that C-avitaminosis is a determining factor.

As regards the resistance of scorbutic guinea-pigs to experimental infection, Findlay (1923), Werkman, Nelson and Fulmer (1924), Grant (1926) and Schmidt-Weyland and Koltzsch (1927) recorded a slight increase in susceptibility. Findlay ascribed this to the degenerative changes and feeble leucoblastic reaction seen in the bone-marrow of guinea-pigs suffering from chronic scurvy. Werkman, Nelson and Fulmer stressed the association between lowered resistance and lowered body temperature.

The observations of Zinsser and Castaneda (1931) on the increased susceptibility of guinea-pigs and rats on a vitamin-deficient diet to experimental typhus infection may be referred to here. It is probable that the guinea-pigs were suffering from some degree of C-avitaminosis; but the fact that rats, which are generally regarded as being relatively insensitive to the deprivation of this vitamin, showed the same decrease in resistance makes it difficult to assess the significance of these results.

McCullough (1938) recorded an increased susceptibility to infection by *F. necrophorus* in deficient guinea-pigs, which only became evident when the scurvy was severe; the administration of Vitamin C was followed by prompt recovery. In man, major deficiency is associated with a retardation of fibroblastic activity and of wound healing (see Hunt

clapses for the breakdown and oxidations to proceed to completion. Soil polluted with sewage similarly "purifies itself."

With increasing population densities the disposal of sewage by dilution becomes unsatisfactory because a body of water is not infrequently a water supply to a neighboring community. Some form of treatment, then, becomes obligatory, in other words, the decomposition is made to take place in whole

water. In practice,

by a period of anaerobic digestion, then a period of aerobic oxidation. Treatment may be complete even through nitrification, or the partially treated sewage may be disposed of by dilution.

When the disposal of fecal material is an individual or family problem the mechanics involved are somewhat different, but the processes of decomposition and oxidation are essentially the same whether a privy, cesspool or septic tank is used.

It will be noted that, although sewage treatment is basically a bacteriological process, the pathogenic bacteria are not involved; their presence is not taken into consideration, nor is there any effort to destroy them except in the rare instances in which the effluent from a complete treatment plant is chlorinated. In one sense, then, sewage treatment is not directed toward the control of water-borne disease. The fact that it is treated, however, is of considerable significance in this connection. When sewage is disposed of by dilution, the typhoid bacillus and related microorganisms do not multiply; rather, a decline in numbers sets in immediately, and these bacteria do not survive as long in water as in soil, probably not more than a few days or a week. It is probable that they tend to disappear equally rapidly during sewage treatment, although there is no assurance that pathogens are absent in the effluent from treatment plants. Clearly then, fresh pollution is more dangerous than past pollution, and, in a sense, treatment obviates the possibility of such fresh pollution. The economic and esthetic aspects of sewage treatment are, of course, another matter.

pantothenate and pyridoxine, but not riboflavin (Axelrod *et al.* 1947); thiamin and biotin (Carter and Axelrod 1948); pyridoxine (Agnew and Cook 1949); pyridoxine, but not pantothenate or riboflavin (Stoerk *et al.* 1947); pantothenate (Ludovici *et al.* 1949); folic acid and tryptophan and nicotinic acid but not cyanocobalamin (Ludovici and Axelrod 1951); pyridoxine, pantothenate, thiamin, riboflavin, folic acid, but not nicotinic acid (Wertman *et al.* 1951, 1952); pantothenate (Giunchi *et al.* 1953). The different experiments were not of course all strictly comparable; but pyridoxine deficiency is consistently reported as impairing antibody production. Folic acid and biotin deficiencies and, with one exception, pantothenate deficiency are also definitely depressant. Riboflavin and thiamin deficiency have less well established effects.

In the mouse, Ruchman (1946) found that lack of pyridoxine, but not of thiamin or riboflavin, was depressant; and in the chick, Little, Oleson and Roesch (1950) that folic acid, but not cyanocobalamin, decreased immunizability.

The evidence with regard to the immunological consequences either of excess or deficiency of Vitamin C is more confusing.

Lesné and Dreyfus (1911) and Zolog (1924) contended that in guinea-pigs deficiency was associated with diminished sensitivity to anaphylactic shock. Cohen (1938) was unable to confirm these findings (see also Sartori 1925, v. Nickerk 1937). Several observers report a prophylactic effect of excess Vitamin C in guinea-pigs, both in the whole animal, and in isolated sensitized tissues (Lemke 1936, Solomonica 1936, Ungar, Parrot and Levillain 1937). Hochwald and Schwartz (1937), Raffel and Madison (1938) and Storck (1939) were unable to confirm these findings, and Dragstedt (Dragstedt *et al.* 1938) failed to find any effect of Vitamin C on hypersensitive dogs. Similarly with antibody formation; Juszat (1936b) and Madison and Manwaring (1937) recorded enhancement of precipitin response in rabbits, and Raffel and Madison (1938) in guinea-pigs given excess Vitamin C. Hochwald and Schwartz (1937) found no enhancement in guinea-pigs immunized with horse serum, and Madison, Fish and Frick (1938) no effect on the response to bacterial antigens. Long (1950), however, recorded a 30-fold depression of diphtheria antitoxin response during the immunization of guinea-pigs on a diet deficient in ascorbic acid, compared with control animals given either an ascorbic acid or a cabbage supplement. Cabbage supplements were also found by Hartley (1948) to improve antitoxin response in the guinea-pig in proportion to the amount given. The active factor in the cabbage is unknown. (For a discussion of the relation between Vitamin C and serum complement, see Chapter 7.)

If we attempt to assess the significance of the data at present available with regard to the influence of variations in vitamin intake on resistance to infection, we shall conclude (1) that an excess of any vitamin over the normal dietary requirements has no consistently demonstrable effect on resistance; and (2) that certain gross vitamin deficiencies are associated with a significant decrease in resistance. In some cases the effect is indirect, in that the deficiency has impaired the intake of protein and calories, so that general inanition, not a particular deficiency, is the immediate cause of lowered resistance. When inanition is as far as possible excluded, it appears that deficiency of Vitamin A, but not of Vitamin D, decreases resistance to some extent. As regards the water-soluble vitamins, resistance to bacterial and rickettsial infections appears to be lower in riboflavin, pantothenate and folic acid deficiencies. Resistance to certain neurotropic viruses is increased by thiamin and pantothenate deficiencies. Lack of other B vitamins and of ascorbic acid may also decrease resistance, but the evidence is more divergent. The resistance of the guinea-pig is most readily affected by ascorbic acid deficiency, as might be expected of an animal that does not itself synthesize this vitamin.

It is clear that we cannot generalize for infections as a whole; each vitamin

THE BACTERIOLOGY OF MILK AND FOOD

MILK¹

As a vector of infectious disease, milk differs from water in that it is an excellent medium for the growth of many pathogenic bacteria, and from other foods in that it is the only food of animal origin that is consumed in large part in the raw state. Since large quantities of milk are consumed—it is estimated that about 16 per cent of the average dietary in the United States consists of milk and milk products—the importance of this substance in the transmission of disease is evident. The diseases transmitted by milk are: first, diseases of cattle transmissible to man and including bovine tuberculosis, undulant fever, foot-and-mouth disease and streptococcal infections from infected udders; and, second, diseases of man in which the milk serves as the link between man and man, such as typhoid fever, septic sore throat, scarlet fever, diphtheria and, rarely, certain other diseases, such as poliomyelitis.

Sources of Bacteria in Milk. Unlike water, milk has no native bacterial flora, and it is probable that milk as secreted into the udder of a healthy cow is sterile. The milk in the udder is, however, rarely if ever bacteriologically sterile, for the microorganisms invade the udder via the milk ducts of the teats and the first portion of the milk drawn (fore-milk) always contains more bacteria than the last (strippings). There is, furthermore, no bacterial flora that is characteristic of milk; the presence of microorganisms is always a consequence of contamination and the types of bacteria found are determined by the source of contamination. From this point of view the bacteria of milk fall into two groups: first, those which are present in the tissues of an infected cow and find their way into the udder, and, second, those which enter the milk, usually after it is drawn, from sources external to the animal.

Bacteria from Infected Cattle. Of these microorganisms perhaps the most important is the *tubercle bacillus*. These bacteria get into the milk directly as a consequence of tuberculosis of the udder, which occurs in 1 to 2 per cent of infected cows, and indirectly by contamination with cow manure when the infectious sputum is swallowed and discharged with the feces. In either case the milk is infective for man, the bovine variety of the tubercle bacillus giving rise, as a rule, to bone and joint rather than pulmonary tuberculosis (p. 631). Milk may, of course, be infected with human tubercle bacilli from infected persons. A high proportion of the former type of infection occurs when the transmission of this disease is allowed to occur. The disease may be controlled at its source, i.e., by the elimination of infected cattle from dairy herds, a practice which is practically universal in the United States.

¹ Hammer: *Dairy Bacteriology*. 3rd ed. John Wiley and Sons, New York. 1948.

Three to six days after an intracerebral dose of virus the animals were exercised to the point of fatigue by swimming in water at 39° C.; the incidence of the disease and the severity of paralysis were higher in these than in control animals, but immersion in the water without exercise had a similar effect. That the chilling incidental to immersion may have been operative was evident from the result of cooling the animals some 11–12° C. by immersion for 30 min. at 17° C.; the incidence of the disease was thereby doubled. More direct effects of fatigue are demonstrable; for example, Rosenbaum and Harford (1953) raised the incidence of disease and the death rate in mice that were made to exercise for one day preceding, and on each day after an intracerebral injection of poliomyelitis virus.

The Effect of Variations in Temperature, Humidity and Other Physical Conditions of the Environment

The evidence available under this head is concerned mainly with the effect of these environmental factors on the first-line defence mechanisms of the kind considered in Chapter 45. Arnold and his colleagues (Arnold 1927*b*, 1928, 1929, Arnold and Brody 1927) studied in considerable detail the effect of high temperature, especially when associated with high humidity, on the gastro-duodenal bactericidal mechanism of the dog. They found that such conditions were associated with a decrease in gastric secretion, a consequent fall in the acidity of the gastric and duodenal contents, and an increased passage of bacteria from the stomach or duodenum to the caecum.

There are in the literature many other records of experiments on the effect of temperature and humidity on resistance to infection (see McDowell 1923, Khigler and Oltzki 1931, Robertson and Weld 1932, Nishikawa 1935), but the number of animals in the comparable groups are so small, and the effects of these two factors seem so difficult to disentangle, that the significance of many of the results reported cannot be assessed.

Sulkin (1945) emphasizes the contradictory results obtained in many experiments, even with the same species of animal and the same species of parasite. The general indication, however, with a number of types of infection, is that exposure to low temperatures, if it has any effect, decreases the animal's resistance. But the effects are often peculiar to the conditions of the experiment. Chilling may directly affect the multiplication of the parasite, or the defence mechanisms; but it may also inhibit the development of symptoms of the disease without materially affecting the degree of parasitism. We may note a few examples.

In the chick embryo, Beveridge (1944) reported that infections with influenza virus by the chorio-allantoic route were less effective in eggs at 39° C. than at 37° C., but the change in temperature did not alter infectivity via the yolk sac or amnion. Sim (1949) recorded a lowered resistance to and greater generalization of infection by vaccinia virus at subnormal incubation temperatures, the effects of which could to some extent be reversed by restoring the eggs to optimal temperatures, and Khigman, Crane and Norris (1951*a*) reported that cryptococcal infections of the embryo disappeared more rapidly at 40° C. than at 37° C.

With influenza virus infection of mice induced intranasally, Sulkin (1945) observed no difference in the mortality of animals kept at 13° C. and 25° C., though the pulmonary lesions were less at the higher temperature. Holtman (1946*a*) acclimatized mice to temperatures of 13° C., 22° C. and 32° C., both before and after infection with poliomyelitis virus, and found a direct relation between the survival time and environmental temperature, as though the higher metabolic rate in the warmer animals had facilitated infection with the virus. Mills and Schmidt (1942) found that mice acclimatized at about 20° C. survived a lethal dose of pneumococci for twice as long as mice acclimatized to 32° C.; though all mice had the same body temperature. Nevertheless, according to Junge and Rosenthal

A bovine variety of *Brucella melitensis*, the causative agent of undulant fever (Chapter 23), infects cattle, producing the disease contagious abortion (the bacterium is sometimes designated *Brucella abortus*). This microorganism is excreted in the milk and infects man, producing a mild type of undulant fever. The caprine variety of this bacterium which is present in the milk of infected goats produces a much more severe disease in man. Undulant fever, like tuberculosis, may be controlled by control of the disease in the animal reservoir of infection.

The virus of foot-and-mouth disease, a virus disease of cattle, is excreted in the milk and is thus transmitted to man. The disease in man is mild, however, and not of great public health importance. More important are the streptococcus infections of the udder, designated garget or mastitis. The *Hotis test* is commonly used for the detection of mastitis; it consists of incubating fresh milk in the presence of 0.025 per cent bromocresol purple for twenty-four hours at 37° C. A positive reaction, the formation of yellow flakes on the side of the test tube, is dependent upon the presence of the streptococci and of agglutinins in the milk, the growing bacteria are clumped by the antibody and the acid reaction results from the fermentation of lactose. The indeterminacy of streptococcus species, coupled with the fact that the same type of streptococcus may produce more than one disease (p. 367), makes it difficult to evaluate the significance of streptococcus mastitis to milk-borne disease. Milk-borne epidemics of septic sore throat, however, are not infrequently associated with acute udder inflammation in the dairy herd and the massive and continuous infection occurring in some of the outbreaks indicates that the udders of the cattle were infected. It has been suggested that the streptococci of scarlet fever may proliferate, with or without symptoms, in the udder, and epidemics of human streptococcal infection, septic sore throat and scarlet fever, may occur,² though it is probable that in most instances milk-borne scarlet fever is a consequence of direct human contamination. It may be noted that the udder may be infected occasionally with diphtheria bacilli, which produce small external ulcers, but this is an uncommon occurrence.

Bacteria from External Sources. When milk is collected under ordinary conditions, the udder bacteria form but an insignificant fraction of the total number of microorganisms in the milk. The skin of the cow, the hands of the milker, the vessels used for collection, and the dust of the cow barn all contribute their quota to the number of bacteria found immediately after milking. If milk is obtained with aseptic precautions, it contains only a few hundred (200 to 400) bacteria per milliliter; collected with somewhat less care, it may contain a few thousand (2000 to 6000); with careless manipulation, even freshly drawn milk may be highly contaminated (30,000 to 100,000 per milliliter). If milk is kept at 0° C. (32° F.), it shows a decrease in the bacterial content during the first few hours, but at higher temperatures the rate of multiplication is high and, when richly seeded at the outset, enormous numbers of bacteria result.

The non-pathogenic bacteria that are present in milk are often differentiated on a physiological basis into the following groups:

- (1) the acid forming bacteria,

² Evans. Jour. Inf. Dis., 1946, 78 18.

non-infective doses of pneumococci would infect the lungs of rats when introduced together with mucin; and that though chilling by itself did not lower the resistance of rats to intraperitoneal pneumococci, it greatly increased the incidence of pneumonia in rats inoculated intranasally with mixtures of pneumococci and mucin. They concluded that chilling, by increasing the aspiration of mucous secretions from the upper respiratory tract, might favour the occurrence of pneumonia.

Though they are not concerned with the direct effect of cold, we may note the experiments of Locke (1937) who observed that the more rapidly rabbits recovered their body temperature after artificial chilling, the greater was their resistance to subsequent intravenous and intradermal infection with pneumococci. Here the chilling was employed as an independent test of the physiological response of the animals to an adverse environment. Duerschner, Muschenheim and their colleagues (Hardy *et al.* 1943, Duerschner *et al.* 1943, Muschenheim *et al.* 1943) reported upon the effect of severe chilling in experimental tuberculosis and in pneumococcal infections. Rabbits and guinea-pigs were held under anaesthesia for 6 to 24 hours at 4–8° C. twice weekly for several weeks. The treatment had no effect on the development of tuberculosis in guinea-pigs, though there was a long delay in the appearance of skin sensitivity to tuberculin. The response of chilled and normal rabbits to an intradermal lethal dose of virulent pneumococci was similar, except that the local lesions were smaller in the chilled animals. When less virulent pneumococci were injected, chilling resulted in inhibition of the local lesion, and a fatal bacteraemia. The rapid invasion of the blood stream did not appear to be solely due to the absence of a local response, for in other experiments chilling was found to reduce the minimal lethal dose even of intravenously injected pneumococci (see also Bruneau and Heinbecker 1944).

Ellingson and Clark (1942) reported a series of experiments to test the response of various defence mechanisms to temperatures greater than normal. In rabbits the artificial induction of a severe fever (41.5° C.) slightly reduced the antibody response during immunization with various antigens. It also produced a slight acceleration of the rate of disappearance, and presumably, of destruction of antibodies in the blood stream. Phagocytosis of *Staph. aureus* by human and guinea-pig leucocytes was only slightly depressed at 42° C.; and in rabbits injected intradermally with lethal doses of virulent pneumococci, the maintenance of artificial fever until the infection itself reached the febrile stage made no significant alteration in death rate, survival time, or degree of bacteraemia.

The temperature relations of *in vitro* phagocytosis were also investigated by Clark and his colleagues. With guinea-pig leucocytes, for example, both opsonization and phagocytosis of staphylococci rose to a maximum with rise in temperature from below 37° C. to 42° C., and declined sharply with further rise. But in changing from 37° C. to 32° C. the efficiency of phagocytosis did not decrease by more than 10–15 per cent. (see Zarafonetis, Harmon and Clark 1947). As regards the clearing mechanism of the reticulo-endothelial system, the clearance of carbon particles from the blood of rats is reported to be impaired in rats kept at a body temperature of 22° C. to 26° C. (Halpern *et al.* 1951).

Among other physical agencies mention may be made of the possible effect of ultraviolet irradiation of the body surface, since this procedure has been advocated as a means of increasing resistance to infection. We have already noted (p. 1349) that Colebrook, Eidenow and Hill (1924) demonstrated a temporary increase in the bactericidal power of the blood as the result of exposure to ultraviolet rays, and a similar effect after exposure to dark heat, or to the blistering of the skin with a mustard plaster. The general experience of the beneficial effect of sunlight as enjoyed under optimal natural conditions, combined with such observations as the above, made it natural to inquire whether any isolated constituent of the solar radiation, and particularly the rays of short wave-length, would produce a significant increase in resistance to infection. Some favourable views have been recorded (Maughan and Smiley 1928, 1929, Hill and Laurie 1931); but the balance

- (2) the alkali-forming bacteria,
- (3) the proteolytic bacteria and
- (4) the inert bacteria.

The first group includes the fermentative bacteria, and the most common type of fermentation is the lactic acid fermentation, the process by which milk usually sours under natural conditions. A variety of bacteria may be responsible, among them such familiar forms as *Staphylococcus aureus*, *Streptococcus pyogenes* and *Bacterium coli*. A few species, however, are commonly active in the natural souring of milk, and these may be divided into two groups. One of these is comprised of the capsulated gas-forming bacilli of the *Bacterium (lactis) aerogenes* type, which are closely related to *Bact. coli*, differing principally in their possession of capsules, lack of motility, and ability to produce gas from potato starch. The second type, a streptococcus, *Streptococcus lacticus* (or *lactis*), is abundant in naturally soured milk, particularly when the acidity is high.

Lactic acid milks, regarded by some as having therapeutic value in the treatment of certain intestinal disorders, have been prepared by the inoculation of *Lactobacillus* species such as *acidophilus* and *bulgaricus*. The lactobacilli, however, are commonly found in the fermentation of ensilage and are present in small numbers in the human mouth and intestinal tract and are not ordinarily responsible for the natural souring of milk.

Although lactic acid is commonly the predominating acid in the fermentation of milk, the formation of butyric acid is observed occasionally. This is generally a consequence of the presence of the anaerobic butyric acid bacteria, but may be brought about through the agency of certain aerobes closely allied to *Bacillus subtilis*.

The spontaneous alcoholic fermentation of milk is less usual under natural conditions than either the lactic or the butyric, and the preparation of certain alcoholic beverages is dependent upon the artificial production of this form of milk fermentation. Koumiss, a drink prepared by Tartars by the alcoholic fermentation of mare's milk, and kefir, an effervescent sour milk prepared by inhabitants of the Caucasus from the milk of cows, goats and sheep, are both prepared by the inoculation of fresh milk with old koumiss in the first instance and with "kefir granules" in the second. The bacteriology of the koumiss fermentation is not well known, but in the case of kefir both a bacterium and a yeast appear to be involved. Some species of yeast, it may be noted, are able to effect the alcoholic fermentation of milk in pure culture.

The *alkali-forming bacteria* are those organisms which do not ferment lactose but, presumably, act upon the nitrogenous substances present with the liberation of ammonia. When typhoid and paratyphoid bacilli, for example, are cultivated in litmus milk no effect is apparent beyond a slowly increasing alkalinity. Certain other bacteria, such as some of the aerobic spore-forming types, also produce lipase and decompose the fats present, converting the milk to a yellow, transparent fluid.

The *proteolytic bacteria* also produce an alkaline reaction and, in addition, hydrolysis of the milk proteins. Two enzymes, or groups of enzymes, are responsible, one, a rennin-like enzyme, precipitates the protein with the formation of a soft curd, and a second, casease, brings about hydrolysis of the protein

to escape from the view that they must have been due to synchronous transient fluctuations in the resistance of the mice, but these fluctuations showed no definite seasonal distribution.

Even if the occurrence of seasonal variations in resistance were clearly established, it would be an exceedingly difficult task to disentangle the various factors involved; and without such disentanglement there could be little hope of intelligent interference. The vitamin content of foodstuffs, and many other dietetic variables, are subject to seasonal influences; the condition of the nasal mucosa and the efficiency of the gastro-duodenal bactericidal mechanism are, as we have seen, affected by changes in temperature and in humidity; and there is little doubt that many other types of physiological response, of which as yet we know little or nothing from the immunological viewpoint, may be subject to influences of a similar kind. Until our knowledge of the relative significance of these factors, working in isolation, is much more accurate and detailed than it is at present we can hardly hope to construct a useful working chart of the total effect of the environmental changes associated with the changing seasons. (See Aycock *et al.* 1945).

The Effect of Certain Chemical Substances in Enhancing Bacterial Infection

We may include in this chapter a brief survey of a series of observations that have, during recent years, focussed attention on certain chemical substances that play a significant part in the local pathogenesis of infective lesions. Some are important because they play a part in the infective hazards of the human and animal environment, others because they throw light on the mechanisms of immunity.

Calcium salts.—We may begin with the observations of Bullock (Gye) and Cramer (1919) on the effect of calcium salts in certain anaerobic infections, and the later studies of Fildes (Fildes 1927, 1929*a, b*, Knight and Fildes 1930, Campbell and Fildes 1931) Bullock and Cramer found that ionizable salts of calcium, inoculated together with the washed spores of *Cl. welchii*, of *Cl. tetani* or of certain other anaerobes, led to the development of the corresponding infections in their most typical and fatal forms, whereas the washed spores alone showed no tendency to develop in the tissues after inoculation. The chlorides of sodium, potassium, ammonium, strontium or manganese had no such effect. They were unable to determine the exact mechanism by which this effect, to which they gave the name *kataphylaxis*, was brought about; though they were able to show that it was not due to an absence of leucocytes from the lesions, or to a lack of phagocytic activity on the part of the cells that collected at the site of inoculation. Fildes (1927), attacking the particular problem of experimental tetanus in the guinea-pig, studied the vegetation of spores in the normal testicle, after ligation of the blood vessels. He found that the injection of tetanus spores into the ligated testicle was followed by a rapidly fatal toxæmia, indicating rapid vegetation in the tissues. Comparison of sections from ligated and unligated testicles, at various intervals after the injection of the spores, showed that active vegetation had occurred in the ligated testicle at a period when emigration of leucocytes was at its earliest stage in the unligated

 oxidation-reduction potential of the tissue fluids under different conditions using suitable indicator dyes. He found that oxidized methylene blue injected into the subcutaneous

which, when complete, results in the conversion of the milk to a clear fluid, a process sometimes termed peptonization. Peptonization, however, does not follow precipitation when the microorganism does not possess casease. The bacteria producing these changes include spore-forming aerobes such as *Bacillus subtilis*, certain strains of staphylococci, *Proteus vulgaris* and others. Proteolysis may occur in heated milk in which the non-spore-forming lactic fermenters have been destroyed, leaving the more resistant spore-forming proteolytic forms.

The "Diseases" of Milk. A series of unusual or abnormal changes, sometimes called "diseases" of milk, are produced by certain bacteria which occasionally find their way into milk. "Blue milk" (*Bact. cyanogenes*), "red milk" (*Bact. prodigiosus*, *Bact. erythrogenes*, et al.) and "yellow milk" (*Bact. synxanthus*) are caused by the presence of various chromogenic bacteria. "Bitter milk," characterized by a bitterness that sometimes develops after a short interval, is likewise due to the products of certain microorganisms. Milk sometimes suffers from a ropy or slimy fermentation which, under most circumstances, is regarded as undesirable, although such a fermentation is intentionally produced in the manufacture of Edam cheese in Holland through the action of a particular species of streptococcus.

The *inert* bacteria are those which produce no visible change in milk. These include certain non-pigment-forming bacteria from water and other sources, and, in addition, most of the pathogenic bacteria that find their way into milk. Such dangerous contamination, then, is inapparent without bacteriological examination.

The Pathogenic Bacteria from External Sources. The multiplicity of sources of contamination results in the heterogeneous bacterial flora that may be found in milk. It is important from the hygienic view that, in addition to microorganisms of soil and water, the bacteria carried by man have relatively ready access to milk. The opportunity for contamination with the bacteria of human disease is, then, ever present, not only when the milk is drawn but throughout its handling until it reaches the ultimate consumer. Contamination may take place directly, as in the case of scarlet fever and other streptococci or diphtheria bacilli from the throat and typhoid bacilli from the hands of infected individuals, or it may be indirect, as when the water used to wash the milk cans is contaminated with typhoid bacilli. In any case, the microorganisms do not simply survive, as in water, but actively multiply and may be present in huge numbers in pooled milk of which but a single part was originally contaminated.

Clearly, then, the most important factors which govern the number of bacteria which may be present in milk are, first, the kind and degree of initial contamination and, second, the temperature at which the milk is kept. The production of hygienically satisfactory milk, therefore, involves cleanliness in the first instance, and immediate cooling and storage at a low temperature in the second. Practical experience has more than adequately proved the significance of these points.

The Bactericidal Property of Fresh Milk. As indicated above, the number of bacteria present in freshly drawn milk frequently shows an initial decrease. The extent of this diminution is, perhaps, exaggerated by plate

dissolved in the tissues, and only when dissolved does it exert its injurious action. Silica crystals coated with oxide of iron are not dissolved in the tissues, and they remain inert and harmless.

The pathogenesis of the lung lesions of silicosis, and the association of this condition with tuberculosis, have been studied in numerous experiments in which dusts have been brought in contact with the lung tissue of guinea-pigs or rabbits, either by repeated or prolonged inhalation, or by the direct injection of a suspension of the dust into the trachea (Kettle 1930).

An interesting experiment was recorded by Gardner (1930). Guinea-pigs were infected, by inhalation, with a strain of tubercle bacillus of unusually low virulence, which normally produced in these animals a retrogressive type of tuberculosis confined to the lungs and bronchial glands. The infection was practically never fatal. When animals so infected were exposed for 8 hours a day to quartz dust an entirely different picture was produced. After 3 to 5 months the bacilli in the lungs began to proliferate actively. The infection spread to all parts of the lungs and to the abdominal viscera, producing large and progressive lesions. The bacilli had not become more virulent, since cultures isolated from the dusted animals produced the usual type of retrogressive tuberculosis when administered to normal undusted guinea-pigs. Vorwald and Delahant (1938) recorded not only that tuberculosis in the guinea-pig and rat developed with greater vigour in animals treated with silica, but that the immunizing effect of heat-killed tubercle bacilli was inhibited by the simultaneous injection of silica.

It was generally assumed that the silica, and the lesions it produced, sensitized the tissues to tuberculous infection. The silica, that is to say, was regarded as the primary active agent. Kettle (1934) showed that this view needed considerable modification.

Different groups of guinea-pigs were injected intratracheally with a suspension of silica alone, a suspension of avirulent tubercle bacilli alone, and a mixture of silica and avirulent

bacilli alone produced relatively little tissue reaction. The mixture of silica and avirulent bacilli produced a characteristic nodular tuberculo-silicosis, closely similar to the human disease. It would seem that the typical silicotic lesions are induced not by silica acting on a normal lung but by the joint action of silica and some bacterial infective agent; and Kettle suggested that the natural human disease should be known as infective silicosis.

Histamine and Adrenaline.—Finlley (1928) tested the hypothesis that the localization of pathogenic bacteria, or of filtrable viruses, at the site of local tissue injury might be the result of the liberation of histamine, or of histamine-like substances, from the injured tissues, leading to a localized dilatation of the capillaries and an increased permeability of the capillary endothelium. Animals of a susceptible species were inoculated intravenously with an infective agent—the virus of fowl-pox, or of vaccinia, or of the Rous sarcoma, *Staph. aureus*, *Str. haemolyticus*, or the pneumococcus, and a 0.18 per cent. solution of histamine base in buffer, given intracutaneously, and control injections of buffer alone. In all cases the lesions in the histamine sites were more frequent and more severe than in the control sites. These results exemplify a general conclusion, reached by Burrows (1932) in his monograph on the localization of infection, that damage, even relatively transient, to the vascular endothelium leads to settlement of blood-borne organisms at the site. The rôle of histamine, or other substances of endogenous origin, in promoting local antibacterial defence by increasing capillary permeability, is less clear; our own observations (unpublished) indicate that it has little effect when given intracutaneously together with the bacteria under test. The importance for defence of a free exudation, of both blood fluids and leucocytes, is, however, evident in the work of Evans, Miles and Niven (1948) on intracutaneous adrenaline, doses sufficient only to constrict the skin vessels for two hours, without subsequent damage to the tissues, impeded all leucocytic emigration for that period, and were sufficient to enhance the infectivity of simultaneously injected staphylococci by 10- to 100-fold, and of *Cl. septicum* by over a million-fold.

counts; the various antibodies are present in the milk, not only the bactericidal substances but the agglutinins as well, which, by clumping the bacteria, may bring about decreased plate counts. That freshly drawn milk is both bactericidal and bacteriostatic, albeit to a mild degree, is, however, definitely established. This activity is thermolabile, being destroyed in fifteen minutes at 75° C. and in two minutes at 80° to 90° C., and disappears a few hours after the milk is drawn.

MILK-BORNE EPIDEMICS OF DISEASE*

Disease	Outbreaks		Cases

The Determination of the Quality of Milk. By far the best index of the quality of milk is the number of bacteria it contains. The bacteria present are, in all cases, a result of contamination, and hence these micro-organisms are reliable indicators of cleanliness and care and are generally used for this purpose.

Plate Counts. The total bacterial count of a milk is, then, a reflection of its hygienic quality, and the plate count has been, and still is, widely used in the bacteriological grading of milk. Standardization of the media and of the technique is, of course, necessary for comparable results. A standard procedure has been developed under the auspices of the American Public Health Association, whose publication³ may be consulted for the details.

Standards of milk quality in terms of plate counts are in general use but vary from one locality to another. In some instances more than one grade of milk is allowable; for example, a "Grade A" milk may contain not more than

³ *Standard Methods for the Examination of Dairy Products* American Public Health Association. 9th ed., 1948. For a discussion of current practical application of these methods see Black: *Pub. Health Rep.*, 1943, 58:1605, 1641, 1681.

Mucin.—Nungester and his colleagues (1932, 1936) noted an exaltation of pathogenicity of pneumococci and streptococci when injected intraperitoneally with a suspension of hog gastric mucin. Mucin was particularly effective with bacteria which, like meningococci and gonococci, are not pathogenic to laboratory animals, and are lethal only in doses in which the bacterial toxin is active.

and Castles 1936, 1937. A similar exaltation of pathogenicity was observed in *H. influenza* (Fothergill, Dingle and Chandler 1937), *Salmonella typhi* (Rake 1935, Buttle *et al.* 1937), *H. pertussis* (Silverthorne 1938), and *Staph. aureus* (Anderson and Oag 1939), but not in *Myco. phlei*, "*B. anthracoides*," *Myco. smegmatis*, *Str. viridans* or *Bact. coli* (Anderson and Oag 1939). Human, guinea-pig and rabbit serum, and dextran are also active, as are (Miller and Castles 1936, Anderson 1935a).

The exaltation of pathogenicity produced by the mucin was not accompanied by any demonstrable change in the virulence of the bacteria, but was clearly due to some action on the defence mechanisms of the animal. The efficacy of the mucin has been variously reported as due to its viscosity and power to inhibit intraphagocytic digestion of the bacteria (Nungester *et al.* 1936, McLeod 1941); to its power to injure the defensive cells and inhibit phagocytosis (Miller and Castles 1936, McCabe and King 1951); to its interference with sensitization of the bacteria by antibody (Keefer and Spink 1938); to an anticomplementary effect (Orskov 1940); to an aggressin-like action, inhibiting the chemotactic emigration of leucocytes (Ercoli *et al.* 1945); to an increase in capillary permeability leading to fibrinous exudation that blocks further leucocytic emigration (Sandage and Stark 1949, Gale and Elberg 1952b); and to a combined anticomplementary and anticoagulant effect (Lambert and Richley 1952). In his review, which should be consulted for details of the earlier work, Olitzki (1948) concludes that the basic effect is the formation by the mucin of a protective coating on the bacteria. However, not all the effects observed can be attributed solely to such an action. The varying degrees of purity and heterogeneity of the mucin preparation used in most of these researches invalidates any firm conclusions that might be drawn. It is clear that viscosity alone is not a determining factor, though viscous undegraded Group A mucopolysaccharide (p 1240) acts like mucin, and loses its activity with its viscosity when hydrolysed (Morgan and King 1943). Landy and Batson (1949) identified the Group A mucopolysaccharide in gastric mucin as the enhancing substance which would be potentiated by adding the ash from the saline-insoluble fractions to the mucin.

The relation of the various components of mucin have been clarified by the extensive analysis made by Smith and his colleagues (H. Smith 1950, 1951, 1953, H. Smith *et al.* 1951, 1952a, b, 1953). Using *Salmonella typhi* infections in mice for assay, they identified three factors: (a) a particulate, insoluble residue (cf. Landy and Batson 1949), which could be replaced by charcoal, kaolin or talc; (b) the viscosity of the medium, which could be provided by substances like blood group mucopolysaccharide, agar, gum acacia or methyl cellulose; and (c) the essential factor, a polysaccharide containing a heparin-like substance, a blood group mucoid, a chondroitin sulphate, and another polysaccharide. Mixing the large-particulate residue, the heparin, the viscous blood mucoid and the chondroitin sulphate reconstituted an active mucin. Except for the fact that heparin is anticomplementary and anticoagulant (Lambert and Richley 1952), the mode of enhancement by these factors is still obscure.

Ionizing Radiations.—The effect on immunity of various ionizing radiations of X-rays have a three-fold bearing: on the exploration of the immune process, on the therapeutic use of irradiation in infective disease, and on the potential hazards of modern warfare. We can only briefly discuss this subject, referring the reader to the admirable review by Tahaferro and Tahaferro (1951), upon which this section is largely based.

There are many clinical reports of a beneficial action of X-irradiation in man, for example, in gas gangrene, peritonitis, and inflammatory lesions of the skin.

30,000 bacteria per milliliter as delivered, and a "Grade B" milk not more than 100,000. There is a steady movement toward more strict requirements, and the maximum number of bacteria allowed is continually reduced. More than one grade of milk is, however, undesirable in that the distribution of inferior milk is allowed, and, when possible, a single standard is preferable. In Chicago, for instance, there is but one grade of milk, and it must not contain more than 10,000 bacteria per milliliter as delivered to the consumer.

*Microscopic Counts.*⁴ Besides the ordinary macroscopic colony count obtained by plating, a microscopic method devised by Breed is of value for many purposes. In the Breed method milk is taken in a capillary pipette discharging 0.01 ml. and is dried over an area of one square centimeter on a glass slide. After washing out the fat with xylol and fixing with alcohol, the film is stained with methylene blue. The number of bacteria per square centimeter is estimated by counting a carefully measured area. The ratio used in comparing the microscopic count with the standard plate count is 4:1, although it is recognized as inaccurate and variable. This direct microscopic count does not involve incubation and has proved of special value in judging the quality of fresh milk as delivered to milk-receiving stations.

Methylene Blue Reduction. If a small amount of methylene blue is added to milk and the mixture incubated, the dye will, in time, be reduced to the colorless leuco base. Although freshly drawn milk has some small power to reduce this and other dyes, the reduction is, for all practical purposes, a consequence of the metabolic activities of contained bacteria. There is, then, a direct relation between the length of time required for reduction and the number of bacteria present, and the measurement of this reduction time provides a useful approximation of the quality of a milk. The method is best adapted to raw milk and has the great advantage that no special apparatus or skill of the operator is required. Although milk cannot be stored for more than a few hours in this way, it is generally agreed that milk which decolorizes in two hours is poor in quality, while that which does not decolorize in eight hours is excellent. Resazurin has been used to some extent in the place of methylene blue.

Bacterium Coli Count. It may be assumed that since *Bact. coli* may be used as an index of the sanitary quality of water, it could occupy a similar position with regard to milk. It will be recalled, however, that water contamination of sanitary significance is fecal, whereas this is not the case with milk; *Bact. coli*, for example, would not be associated with the presence of the diphtheria bacillus in milk. Furthermore, since the great majority of market milks contain cow feces, the estimates varying from 60 to 100 per cent, *Bact. coli* in milk is probably most often of bovine origin. Although the *coli* count has been used widely in the past, the differentiation of these microorganisms is not worth while except under special circumstances that warrant it.

The Isolation of Pathogenic Bacteria. In contrast to water, the isolation of pathogenic bacteria from milk is not only a practical but often a desirable procedure. The presence of tubercle bacilli, for example, can be conclusively shown only through the isolation of these microorganisms, in this instance usually by guinea pig inoculation. Other pathogens, such as hemolytic strepto-

⁴ For a general discussion see Brew and Breed: Amer. Jour. Pub. Health, 1945, 35-683.

milder irradiation would in some circumstances stimulate one or more of the defence mechanisms of the body; but the varied results of attempts to elicit and to analyse this beneficial response to X-rays indicate that we are still far from defining those circumstances.

The Influence of Hormones on Resistance to Infection.

There is little doubt that resistance varies with different states of hormonal balance in the animal body, but the data are for the most part too confused to yield any clear picture of the hormonal effect. The hormonal variations that have received greatest attention in connection with resistance to infection are those of the sex hormones and, within recent years, of the steroid hormones of the adrenals. It is not our purpose to review the literature of sex incidence and mortality in infective disease, or to consider the variations in resistance that accompany puberty, menstruation, pregnancy and sexual senility; or to discuss in detail the evidence for the part played by the adrenal cortex in maintaining or promoting defence reactions to infective microbes; but to give some examples from experimental work illustrating the kind of hormonal effects that have been observed.

Schütze, Gorer and Finlayson (1936) recorded a definite, but inconstantly observed superiority of female mice over male mice in their resistance to infection with *Salm. enteritidis* and *Salm. typhi-murium*; but a male superiority in resistance to infection with *Past. muriseptica*. Watson, Wilson and Topley (1938) also noted that female mice were more resistant than males to the epidemic spread of infection with *Salm. typhi-murium*. There are a few experimental studies of the effect of the female sex hormones on resistance. Rosahn, Hu and Pearce (1936) found that male rabbits were less resistant to vaccinia infection than female, and non-pregnant females less resistant than pregnant females. Jungeblut and his colleagues reported that poliomyelitis virus was inactivated *in vitro* by a preparation from the urine of pregnant mares and by the serum of the same animals. They were unable to obtain any clear evidence of protection by various hormones in experimental poliomyelitis of the monkey (Jungeblut, Meyer and Engle 1934, Jungeblut and Engle 1934). Aycock (1936, 1940, Curley and Aycock 1946), proceeding from the generally held opinion that pregnancy in women predisposes to paralytic poliomyelitis, investigated the effect of oestrogens on immunity in monkeys and mice. Oestrogens protected both normal and castrated monkeys against an otherwise fatal dose of poliomyelitis virus, an effect he attributed in part to the thickening and proliferation of the site of injection—the nasal mucosa—under the influence of the hormone. His observation (Foley and Aycock 1945) that oestrogens decreased the resistance of mice to intranasal instillation, but not to intracerebral injection of the virus, is consistent with this view. Knox (1950) studied the resistance of mice during the whole course of pregnancy and observed a gradually increasing susceptibility to the virus as gestation proceeded, the mice reverting to normal resistance within a few days of delivery. An oestrogen effect on the permeability of the mucous membranes cannot have been the sole reason for this result, because the mice became equally susceptible to oral or intravenous virus. The effect of the hormone is evidently complex depending not only on the state of the animal, but on the nature of the pathogen; thus, oestrogens are reported to decrease, not increase, the susceptibility of mice to *Str. pyogenes* (Foley and Aycock 1944).

A change in a mucous membrane may be responsible for the curative action of oestrin in gonorrhœal vaginitis in children. The cells of the immature vaginal mucosa are poor in glycogen; with the onset of puberty, or with the administration of oestrin, they become rich in glycogen, and superficial keratinization occurs. In the oestrin-treated child with vaginitis, the pH of the vaginal contents shifts from about 7.0 to 4.5-6.0, the

cocci, *Brucella*, etc., may be isolated by culture. The isolation of these bacteria is not, of course, a routine procedure but is frequently carried out when an outbreak of disease is suspected of being milk-borne. The details of the methods employed may be found elsewhere.³

Cell Count and Sediment Test. The number of leucocytes present in a sample of milk and the amount of contained dirt that can be strained out through a standard cotton disc are frequently of value in the assay of milk quality. Excessive numbers of leucocytes are present in the milk from infected udders, and when their presence is noted in Breed smears, mastitis is suggested. The amount of sediment that a sample of milk contains is, of course, an index of the extent to which it has been contaminated and is often, though not necessarily always, correlated with the bacterial count.

The Hygienic Control of Milk. The sanitary quality of milk may be controlled in one or both of two ways: in the first instance, by preventing to a considerable degree the contamination of milk and the multiplication of contained bacteria; and, in the second, by destruction of bacteria, the pathogenic forms in particular, already present in the milk.

Inspection. The periodic inspection of dairy farms is carried out by the local board of health in many places, and, although it does not insure the absence of pathogenic bacteria from milk, it is effective in increasing cleanliness and reducing the numbers of bacteria. A score card is frequently used, and a given dairy farm is rated according to a system of points.

Certified Milk. One of the earliest attempts to avoid the dangers of milk-borne infection was the elaboration of methods designed to safeguard milk at every step in its production, collection and distribution. To this end "Medical Milk Commissions" were established in a number of localities in the United States, usually under the auspices of the local medical society. Milk conforming to certain standards is certified by such a commission to be of high quality. The regulations, which are generally excellent, deal with such matters as the cleanliness of barnyard and dairy; the purity of the farm water supply; the proper sterilization of utensils; and the health of the cows and of the milkers. The bacterial content is limited to 10,000 per milliliter and the milk must be delivered within thirty-six hours.

Certified milk is undoubtedly safer to use than milk collected and transported without suitable supervision, and the work of the milk commissions has done much to improve dairy conditions in many parts of the country. At the same time, raw milk, certified or not, can never be regarded as protected against all chances of contamination; the difficulty—not to say impossibility—of making sure that no typhoid carriers and no persons suffering from a mild case of diphtheria or scarlet fever are ever employed in a dairy is, of course, self-evident. Outbreaks of diphtheria, paratyphoid fever and other diseases have, in fact, been traced to certified milk. For this reason, as well as because of the relatively high cost of production, the use of certified milk remains limited.

Pasteurization. The process of destroying pathogenic bacteria in milk is by far the most satisfactory method of controlling milk-borne infection. The use of a temperature high enough to kill most microorganisms but not so high as to produce radical alterations in the substance heated was first applied by Pasteur to preserving wines without destroying their original flavor or bouquet. Al-

the clinical observations because, as Kass and Finland (1953) point out in their concise review of the subject, the human diseases affected are mostly those without an established infective aetiology, for which no experimental laboratory analogue is known. Nor do they greatly illuminate the function of the adrenal cortex in defence, except to establish that the cells concerned in defence and antibody formation, like many other cellular and biochemical activities of the body, can be modified by excess or defect of the cortical hormones.

The adrenal cortex, unlike most other endocrine centres, is peculiarly and quickly responsive to various stresses. A single stress results in an outpouring of steroid hormones, with characteristic cellular and biochemical changes in the blood and an increase in general resistance of the animal followed by a period of "exhaustion" of the gland. Selye (1950) developed a concept, the "stress" or "adaptation" syndrome, to embrace not only acute reactions, but chronic states where there may be a long continued stage of exhaustion, accompanied by pathological changes in the tissues, which predispose the animal to many diseases, including infections. It is doubtful how far this concept is applicable to all infections, excepting in so far as any manifest infection may be regarded as a disturbance of the adaptive mechanisms of an animal—a disturbance which the adrenals may share in, but not necessarily affect in any decisive way.

There is already a vast literature, both clinical and experimental, about these hormones, and we can cite only a few examples of experimental work, referring the reader to Kass and Finland (1953) for a wider survey.

The cortisones and corticotrophin usually have similar effects, and we shall consider them together. But they differ in one important respect: the second can release only the available endogenous corticosteroids, whereas doses of cortisone can be given that are far in excess of the immediately available endogenous hormones. We shall not therefore expect their action always to be similar.

In experimental infections, the positive results are usually obtained only with pharmacological doses that induce a state of "hypercorticism," characterized among other things by depletion of lymphoid tissue, depression of the reticulo-endothelial clearing mechanisms and of the capacity to form granulation tissue. It is only in the suppression of certain hypersensitive reactions (Chapter 51) that small doses are consistently effective. The large doses, almost without exception, impair the resistance of laboratory animals. Thus in cortisone-treated mice (Hart and Rees 1950), guinea-pigs (Spain and Molonut 1950), and rabbits of a genetically resistant strain (Lurie *et al.* 1951), the lesions of tuberculosis are more extensive, more widespread and less well localized than in control animals. Friedlander (1951) recorded an increase in the incidence of arthritis and death in mice infected with *Str. viridans*, and Mogabgab and Thomas (1952) in the mortality of rabbits infected subcutaneously with *Str. pyogenes*; in the latter, death was associated with bacteraemia, and there were few clinical signs of infection. Cortisone changed mild brucella infection in mice and guinea-pigs into a fulminating and fatal infection, it had no effect on chronically infected animals, presumably because there was an associated high degree of antibody immunity (Abernethy and Spink 1952). It also lights up latent disease; LeMaistre and Tompsett (1952) observed that 82 per cent. of rats from an otherwise healthy stock developed a fulminating *C. murum* infection during cortisone treatment, and Gledhill and Rees (1952) described a spontaneous streptococcal disease in cortisone-treated laboratory mice.

In rabbit syphilis the granulomatous reactions are depressed and the multiplication of spirochaetes facilitated (Turner and Hollander 1950). A similar numerical increase in the pathogen is demonstrable in chick embryos infected with mumps virus (Kilbourne and Horsfall 1951). Among virus diseases we may cite an enhancement of vaccinia lesions in the guinea-pig (Khigman *et al.* 1951b), and in the mouse an enhancement of poliomyelitis (Findlay and Howard 1952), Japanese B encephalitis (Vollmer and Hurlblut 1951), and in-

though still widely used in connection with bottled beer and wines, the process of pasteurization is now used chiefly for the treatment of milk.

The temperature to which milk is raised and the time for which it is held there are, of course, dictated by the heat resistance of the bacterium to be killed. From the beginning attention has been directed primarily toward the tubercle bacillus, and it has been found that this bacterium is killed by exposure to a temperature of 140° F. for twenty minutes. In practice, then, a temperature of 142° to 145° F. for a period of thirty minutes provides an adequate margin of safety, and these are the requirements that are usually specified.⁵ It should be noted that the technical aspects of such treatment of milk on a large scale are of prime importance, taking the form of prevention of foaming, proper design of valves to prevent "cool pockets" and dead ends, and the like. It might be supposed that a higher temperature or longer holding time resulting in a greater margin of safety would be desirable, this is, however, not the case, for if either the time or the temperature is increased alterations take place in the physical state of the milk in which the fat is dispersed into smaller globules and will not rise to the top on standing. Such a disturbance of the "cream line" is, of course, of esthetic rather than sanitary significance.

Considerably higher temperatures and a short holding time have been and still are used to a limited extent. In the so-called "flash" process the temperature is raised to 160° F. and maintained for fifteen seconds, then the milk is immediately chilled, as it is in the "holding" process discussed above. Both time and temperature are difficult to control accurately in the flash process, and this fact, together with the "cooked" taste imparted to the milk, has severely limited the use of this method.

The plate count of milk is tremendously reduced by pasteurization, for not only are the pathogenic bacteria, such as the tubercle bacillus, *Brucella abortus*, streptococci and the like, destroyed, but the majority of other bacteria present as vegetative cells are killed also. The efficiency of the process may, then, be measured in terms of bacterial destruction and, in the last analysis, must be measured this way. Very recently, however, a test has been devised which apparently gives an accurate measure of the efficiency of pasteurization as carried out in practice. The *phosphatase test* is based upon the presence of the heat-sensitive enzyme phosphatase in milk. Since 96 per cent of the enzyme is destroyed by heating to 143° F. for thirty minutes, the amount remaining in a pasteurized milk may be used as an indicator of the pasteurization as carried out. The enzyme liberates phenol from phosphoric-phenyl esters and, as originally proposed, the test consisted of the addition of disodium phenol phosphate and Folin's reagent, incubating eighteen to twenty-four hours, and reading the blue color developed. A variety of modifications has, however, been

in the breakdown of sulphonamido-crysoidin (Prontosil) to yield active sulphanilamide. The hypothesis is generally acceptable on the grounds that (a) for a given infecting agent, *in vitro* activity broadly parallels *in vivo* activity, and (b) the activity of a given drug varies with the species and often with the strain of the infecting organism. If there was a direct stimulation of the body defences, we should expect a greater similarity of action in various infections than is actually the case. The recorded discrepancies between *in vivo* and *in vitro* activity of any one drug and a given bacterium (see, for example, Buttle *et al.* 1937, Gley and Girard 1937) do not necessarily invalidate the hypothesis, for it is seldom possible to make a precise comparison of the concentrations of drugs and drug-antagonizers, and of bacteria, in the test-tube and the tissues, or to assess the contribution made by the tissues to the antibacterial effect.

Sulphonamides.—Various *in vivo* sulphonamide effects on bacteria have been postulated. Capsular degeneration of pneumococci and streptococci was observed by Levaditi and his colleagues (1935a, 1939), by Telling and Oliver (1938) and by Whitby (1938), though Long and Bliss (1937a), Gay and Clark (1937) and Lyons and Mangiaracine (1938) did not observe it in streptococci, nor Fleming (1938b) in pneumococci. Capsular degeneration, it should be noted, may take place with the ageing of a culture of capsulated organisms, and may be distinct from the loss of a capsule that in some cases accompanies $M \rightarrow S \rightarrow R$ variation (Chapter 9). A more commonly reported change is swelling, elongation and distortion of the bacteria, seen, for example, in meningococci (Levaditi and Vaisman 1936) and streptococci (Gay and Clark 1937, Long, Bliss and Feinstone 1939). These "degenerative" changes in the streptococci were not associated with a loss of virulence, though there was a temporary variation from the mucoid to the "matt" colony form. According to Lyons and Mangiaracine (1938) and Lockwood (1938) the sulphonamides induce in streptococci changes that make them more susceptible to phagocytosis. Sulphonamides will induce a mucoid \rightarrow "smooth" transformation *in vitro*, with an associated loss of virulence, but the rate of variation is apparently too slow to be operative in the cure of acute infections (Hadley and Hadley 1941). McKinney and Mellon (1941) isolated relatively avirulent variants of pneumococci from mice treated with minimal curing doses of sulphapyridine. Hartmann (1944) was unable to detect any change in the cultural characteristics of pathogenic *Staph. aureus* during the local treatment of staphylococcal lesions in the rabbit with various sulphonamides.

Sulphonamides inhibit the action of streptococcal hæmolysins and leucocidins *in vitro* (Levaditi and Vaisman 1935a) and in bone marrow culture (Osgood and Brownlee 1938). Huntington (1938) observed a parallel inhibition of hæmolysin formation and growth in streptococci, and King, Henschel and Green (1938) an inhibition of the hæmolysin by concentrations that did not inhibit growth. The suppression, selective or not, of certain synthetic powers by an antibacterial agent is, as Garrod (1938) points out, to be expected, and is brought about by antiseptics as well as chemotherapeutic agents. There is some evidence, however, of a direct antitoxic effect of sulphonamides. The oral administration of 4-nitro-4'-aminodiphenyl sulphone and to a less extent, of sulphanilamide was found by Levaditi and Vaisman (1937, 1938) to protect mice against intraperitoneal injections of the endotoxins of *N. gonorrhææ*, *N. meningitidis*, *Past. avicida*, *Sh. flexneri*, *Sh. dysenteriae*, and *Salm. typhi-murium*. Carpenter, Hawley and Barlour (1938) demonstrated a similar *in vivo* protection against gonococcal and pneumococcal endotoxins, and against staphylococcal toxin and certain clostridial toxins. Hutner and Zahl (1942) confirmed the protective action against *Salm. typhi-murium* endotoxins (but see Buttle *et al.* 1937). The inhibition of exotoxins was not confirmed by other workers (Levaditi and Vaisman 1938, Gross *et al.* 1938, Bayliss 1940, Rigdon and Freeman 1940).

There is little unequivocal evidence for a direct action of sulphonamides on the cellular defences of the animal. Mixtures of defibrinated or heparinized blood with sulphonamides

teurizing temperature. These are the lactic acid formers rather than the pathogenic forms, and pasteurized milk sours in the ordinary way on standing, though a longer period of time is required—i.e., its keeping qualities are improved. If higher temperatures are used, 180° F., the lactic acid bacteria are killed and proteolysis occurs as the milk spoils. Thermophilic bacteria are frequently present in pasteurized milk in great numbers, for the temperature of pasteurization is an incubation temperature for these microorganisms. The slight acid metallic taste occasionally noticeable in pasteurized milk is often attributable to their biochemical activity.

It must be emphasized that the process of pasteurization, while effective in destroying pathogenic bacteria present in milk and, incidentally, increasing its keeping qualities, is not to be regarded as an excuse for the marketing of dirty and highly contaminated milk. There is some evidence, for example, that the growth of enormous numbers of bacteria, albeit nonpathogens in the usual sense, is associated with summer diarrhea of infants. In most cases, therefore, sanitary regulations specify not only the allowable number of bacteria in pasteurized milk as delivered but also an upper limit for raw milk which is to be pasteurized.

The Regulation of Milk Quality. The application of appropriate methods of rendering and keeping milk satisfactory from the hygienic point of view is, essentially, a social and legal problem rather than a scientific one. To this end appropriate ordinances are more and more generally incorporated into the legal structure of the community, and these, when adequately enforced, produce a marked reduction in milk-borne disease. A standard form of ordinance developed by the United States Public Health Service⁸ had in 1938 been adopted by more than 800 American cities. In any case, the grading and pasteurizing of milk has become general in the United States. A survey⁹ has shown that about half the cities of over 1000 population grade milk and permit the sale of one grade of raw milk and one grade of pasteurized milk; of the total volume of market milk about 74 per cent is pasteurized, 99.4 per cent is from tuberculin-tested herds, and 35 per cent from abortion-tested herds. In general, sanitary regulations are somewhat more strict and more rigorously enforced in the large cities. In Chicago, for example, all milk is pasteurized, including certified milk, and this regulation is rigidly enforced.

Such practice has resulted in marked reductions in the number of bacteria in market milk. In 1901 the bacterial content of market milk in New York City varied from 300,000 in the coldest weather to 5,000,000 during the summer months; in Chicago (1904) the counts ranged from 10,000 to 74,000,000, and in Boston (1892) averaged 4,500,000. The incidence of milk-borne disease has correspondingly decreased, for example, in 1907–1915 there were in Massachusetts 2215 cases of typhoid fever which were traced to milk, but in 1919–23 only 297.

Milk Products. Various foods made from milk, such as ice cream, butter, cheese and the like, are potential vectors of disease when made from milk contaminated with pathogenic bacteria. The bacteria tend to die out upon stor-

⁸ Pub. Health Repts., 1926, 41.1604.

(Loewenthal 1939); in streptococcal infections of mice (Behrens 1938, Loewenthal 1939); in experimental staphylococcal infection (De and Basu 1938); in meningococcal infection of mice (Branham and Rosenthal 1937, Branham 1940); in *Salm. typhi* infections of 10-day chick embryos (Weil and Gall 1941); and to a slight extent in *H. pertussis* infection of mice (Bradford and Wold 1939). Colebrook and Moxted (1940) confirmed the findings with regard to the bactericidal power of the blood, but found only a feeble synergy in experimentally infected mice, and that only when sub-optimal doses of sulphonamide were employed.

Macleod, Rogers and Fleming (1939) found that the survival rate of mice and rabbits infected with pneumococci was increased if the animals were actively immunized at the time of the sulphonamide therapy with a single dose of pneumococcal vaccine (see also Chapter 74).

Synergy of this kind also occurs in the treatment of clostridial infections. Under careful controlled experimental conditions, Henderson and Gorer (1940) found a striking synergy of antitoxin and sulphonamide in both prophylaxis and cure of *Cl. welchii* and *Cl. septicum* infections of guinea-pigs. Singer (1940) obtained similar results; the sulphonamides used had no effect on *Cl. oedematis* infection and in this case no synergy of drug and specific antitoxin was observed. Gordon and McLeod (1941), however, employing different experimental methods, observed little curative action of sulphonamides in experimental *Cl. welchii* and *Cl. septicum* infection, and no synergy in combined drug and antitoxin treatment.

The sulphonamides are generally held to be bacteriostatic *in vivo*, restraining bacterial growth within limits that enable the defence mechanisms of the body to eliminate the invader. Some idea of the value of such restraint will be evident from the following calculation. If we assume a division of the parasite every 20 min. and a survival of all daughter cells, in 12 hours a single cell has multiplied to 2^{35} (about 10^{11}), whereas even a partial bacteriostatic effect that reduced division to once every 40 min. would limit the number at 12 hours to 2^{17} , i.e. to a number about 250,000 times 2^{-18} less than that of the uninhibited organisms.

There is thus little evidence of peculiar *in vivo* effects of the sulphonamides on the infecting organism; and little evidence of antitoxic effects, or of direct stimulation either of the non-specific or specific antibacterial mechanisms of the host, at least to a degree likely to make a significant contribution to defence.

Antibiotics.—The same conclusions apply to antibiotics, with certain differences dictated by differences in the mode of action. Some, like the sulphonamides, may act as bacteriostatics, particularly in low concentrations, and depend for their total effect on the co-operation of the tissues; others are directly bactericidal. Among these is penicillin, to which bacteria are most susceptible when they are actively dividing (Chapter 6).

The relation of bactericidal and bacteriostatic action to the host's defences is well illustrated in the papers of Eagle and his colleagues, to which reference should be made for details of earlier work on the subject. In an analysis of the optimal conditions for penicillin therapy, Eagle found that, whereas the number of streptococci or pneumococci at the site of an intramuscular injection in mice rose in untreated animals, in animals given a single dose of penicillin it declined within a few hours, at a rate proportional to the dose of penicillin, and similar to the death rate *in vitro*. Moreover, the curative single dose was proportional to the number of organisms inoculated. When the penicillin concentration in the mouse dropped below effective levels, the surviving bacteria began to multiply, but only after some hours, indicating a residual damage to the bacterial cell. This stage can be reproduced in untreated animals by injecting cocci that have been ex-

"in vitro" the cocci do not begin to multiply freely in the muscle until a bacteri-

age, of course, although it has been found that the typhoid bacillus will survive for three months or more in butter, and tubercle bacilli have been found in butter and certain quick-ripening varieties of cheese. Ice cream may serve as a vector for typhoid fever, scarlet fever and the like. Pasteurization of the mix is customary and generally at higher temperatures than those used for milk. Human infections with foot-and-mouth disease have been traced to contaminated butter and cheese, but the public health significance of these findings is problematical.

FOOD POISONING AND FOOD-BORNE INFECTION¹⁰

The diseases transmitted by milk and milk products may be disseminated by a variety of other foods, in addition to these, however, other types of illness may result from the ingestion of contaminated foods which make up that group of affections designated as food poisoning. The kinds of illness that may result from the ingestion of food may be summarized briefly.

- (1) individual idiosyncrasies;
- (2) toxemia from foods, such as
 - (a) foods naturally poisonous,
 - (b) foods into which poisons have been accidentally introduced and
 - (c) foods containing poisons of bacterial origin formed by
 - 1 *Clostridium botulinum* and
 - 2 staphylococci,
- (3) food borne infection, including both
 - (a) bacterial infections, such as
 - 1 typhoid fever, dysentery, cholera *et al.* and
 - 2 *Salmonella* infection, and
 - (b) parasitic infections.

It will be clear that in some instances food serves simply as a vector in the transmission of diseases such as the parasitic infections and the enteric diseases. In the remainder, however, the clinical manifestations are those associated with food poisoning proper—vomiting, diarrhea, enteritis and a greater or lesser degree of prostration. Although a number of types of food poisoning given above are not bacterial in origin, their clinical symptoms frequently are those of bacterial food poisoning, and these must be considered in any attempt to ascertain the etiology of a given outbreak, even though food poisoning is, in a majority of instances, a consequence of bacterial activity. Hypersensitivity (p 334) to a given food substance, for example, is frequently manifested as vomiting, and an outbreak confined to a family may be the result of familial tendency, similarly, the gastro-intestinal disturbances following the ingestion of naturally poisonous foods such as toadstools, or foods contaminated with poisons such as arsenic or cyanide, are often indistinguishable from those induced by some poisons of bacterial origin.

Food Poisons of Bacterial Origin. Often popularly termed "ptomaine poisoning," poisoning with food containing toxic substances of bacterial origin is very common, probably more so than is generally recognized. The term "ptomaine poisoning" is a misnomer that is both misleading and inaccurate.

¹⁰ Jordan *Food Poisoning and Food Borne Infection* 2nd ed. University of Chicago Press, Chicago, 1931. Dack *Food Poisoning*. University of Chicago Press, Chicago, 1943

the occurrence of antagonism between various pairs of antibiotics. There are reasons (p. 207) for thinking that it is not as important in clinical practice as it appears to be from laboratory investigations. For the therapeutic implication of these phenomena we refer the reader to the papers of Jawetz and Gunnison (1952) and Garrod (1953).

The relation of antibiotics to specific immunity is like that of the sulphonamides, with differences imposed by the more effective direct bactericidal action of certain antibiotics. Harrison (1946), for example, compared sulphonamides and penicillin in rabbits receiving intradermal injections of lethal doses of pneumococci. Penicillin abated the infection when given 4 hours after the cocci; there was no local lesion, and neither agglutinins nor immunity to later re-infection developed. With curative doses of penicillin given 24 hours after the cocci, the lesions resolved, and a high degree of specific immunity developed. Sulphapyridine, on the other hand, given at 4 or 24 hours, was slower in controlling the infection, but a certain immunity developed afterwards. The immunity, however, was less in the "24-hour" group than in the "4-hour" group. It appears that the early penicillin destroyed the cocci before they grew sufficiently to provide an adequate antigenic stimulus, and the late penicillin quickly killed the more numerous cocci, thereby providing a good antigenic stimulus. The early sulphonamide, on the other hand, allowed growth enough to provide a sufficient stimulus, but after later sulphonamide the antibody response was to some extent neutralized by large amounts of capsular substance elaborated as a result of the more extensive and continuing infection. Harrison concluded that penicillin was less dependent on the immune response than the sulphonamide.

According to Miller and Foster (1944) and Kelly and Schnitzer (1945), the combined effect of penicillin and specific antibody is synergic. However, Browning and Calver (1947), working with *Staph. aureus* infection in sulphathiazole- and penicillin-treated mice, concluded that the beneficial effect they observed with α -antitoxin was additive; and Treffers and Muschel (1954) clearly demonstrated that the combined bactericidal action of antibody and complement and chloramphenicol on *Salm. typhi* *in vitro* was not synergic, but purely additive. As regards the impairment of antibody response during antibiotic treatment, several observers have recorded that the rapid elimination of streptococci from the lungs in infection of man reduces the subsequent antibody response (e.g. Rantz *et al.* 1946, Kilbourne and Loge 1948). In the experimental animal, in addition to the work of Harrison discussed above, we may note examples of a similar reduction of the immunizing stimulus of infection in the early penicillin treatment in rats and guinea-pigs infected with pneumococci (Skinses 1948); and in mice infected with *Br. tularensis* and given streptomycin (Chapman *et al.* 1949). Speck and Jawetz (1952) treated mice with penicillin and aureomycin 24 hours after infection with *Str. pyogenes*, and found that the immunity of survivors to reinfection 16 days later was greater in the animals receiving the less effective antibiotic, which in this case was penicillin.

The alternative explanation of a direct suppression of antibody synthesis by the antibiotic has been considered. Green, Wohl and Waife (1951) could demonstrate no suppression by penicillin of the *H*-agglutinin response in man to typhoid vaccine. However, using an indirect indicator of antibody formation, Stevens (1953) reported that the response of rabbits to a protein antigen was depressed by the continued administration of dihydrostreptomycin, terramycin, penicillin and aureomycin. Some rabbits in each group were resistant to this action, and particularly to the last two antibiotics.

Two of the possible effects of chemotherapy, the emergence in the infected animal of drug-resistant strains, and the suppression of the infecting agent before it has grown to the point where it provides an effective antigenic stimulus, have implications not only for the treated individual, but for the herd. The widespread use of an antibiotic in a community might lead in the first case to the establishment of endemic infection with drug-resistant bacteria, and in the second, to the perpetuation of a disease prevalence that in the normal course of events would decline. recovered individuals in the community. emergence of penicillin-resistant staphylococci.

The organic bases such as putrescine, cadaverine, methylamine and the like, which have been called ptomaines and which result from the bacterial decomposition of protein, are not toxic when given by mouth. Neither are other decomposition products toxic *per os*. While a partially decomposed food may be esthetically unattractive, the innocuous nature of the products of decomposition is obvious when one considers the advanced state of decomposition reached by some cheeses. Toxicity is, on the contrary, attributable to the presence of substances synthesized by the bacteria whose presence may or may not be associated with obvious evidence of decomposition of the food substance.

Botulism. Of the toxic substances formed by bacteria in food the most powerful is the toxin of *Clostridium botulinum* (p. 593). In the United States canned foods provide the anaerobic conditions necessary for the germination of botulinus spores which have survived processing, while in Europe meat products, particularly the larger sausages, have been more frequently involved. The microorganism never infects man under natural conditions, and the disease is an intoxication resulting from the ingestion of preformed toxin present in the food substance. The disease is not of great public health importance—about 2000 cases have been reported in all—and the outbreaks are generally limited in scope, often being confined to a family circle of a few individuals. The case fatality is high, however, probably 60 to 80 per cent, and when outbreaks do occur they attract considerable attention. This type of food poisoning differs from the others in that the symptoms are not necessarily gastro-intestinal, the toxin acts upon the peripheral nerves and the symptoms are those resulting from such damage. The use of botulinum antitoxin is discussed elsewhere.

Since both anaerobic conditions and a period of incubation are required for the growth of *Cl. botulinum* and the formation of toxin, fresh foods are not involved in this type of food poisoning. The toxin is destroyed by heat, hence freshly cooked foods do not contain it. Canned foods and certain meat products which are consumed either cold or after simply warming may contain botulinum toxin if the spores of this bacterium were originally present and not destroyed. Commercial processing as now employed in this country is adequate to destroy botulinum spores, and at the present time outbreaks of botulism are frequently attributable to the consumption of home canned, insufficiently heated foods. The presence of toxin is not necessarily associated with obvious signs of spoilage, though it is probable that toxin-containing foods are never entirely normal in appearance, odor and the like.

Staphylococcus Food Poisoning. The marked gastro-intestinal disturbances characteristic of food poisoning are not infrequently associated with the consumption of foods containing starch thickening, such as eclairs, cream puffs, certain types of cake fillings and salad dressings, and the like. Upon bacteriological examination, the incriminated food generally is found to contain enormous numbers of bacteria, sometimes staphylococci, other times bacteria of the colon-aerogenes group, streptococci, *Proteus* and similar microorganisms.

The causal relation of staphylococci, generally, though not necessarily, hemolytic strains of the *Staphylococcus aureus* group, to food poisoning was

by the virus. The insusceptibility, however, appears to be realized at the expense of considerable damage to the nasal mucosa (Schultz and Gebhardt 1942, see also Chapter 87).

The Rôle of the Bacteriophage in Infection and Resistance

This is, perhaps, as convenient a place as any to summarize the available evidence with regard to the rôle played by the bacteriophages in infection and resistance. The relationship between the various types of phage and the bacteria that are sensitive to their action is highly specific, and is usually determined by the nature of the antigenic components situated at the bacterial surface.

The existence of living viruses, specifically attacking various pathogenic bacteria, offered an obvious possibility that they might be employed in the prevention or cure of infective disease. That they can be so employed, and are highly effective, was claimed by d'Herelle (1926); and several observers have reported favourable results in field trials of cholera phage as a prophylactic in India (see Morrison 1932). There are also various observations in the literature with regard to the use of phages as therapeutic reagents in human infections (see Krueger and Scribner 1941); but these are discrepant, and not of the kind that provide us with the evidence we need, though on the occasions when large-scale observations are made with as great a care as the circumstances permit, the results are not encouraging (see *e.g.*, Boyd and Portnoy 1944). Morton and Engley (1945a) consider that, although dysentery phage is prophylactically useful in man, the evidence for a therapeutic effect is inconclusive, and they set out criteria for more stringent tests. These include bacteriological identification of the infecting organism and proof of its susceptibility to the phage used, bacteriological proof of cure, freedom of the control cases from a naturally acquired dysentery phage; exclusion of effects due to changes in other intestinal organisms, and proof that the administered phage reaches the infecting organisms in active form. Aside from a theoretical lethal action of the phage on the infecting bacteria, it is possible that the phage filtrates are beneficial because they act as specific vaccines, since they contain the antigens of lysed bacteria; as stimulants of a non-specific immunity; or as opsonins (see Krueger and Scribner 1941). In this last connexion we may note that MacNeal, McRae and Colmers (1938) demonstrated a substantial opsonic effect when optimal quantities of specific phage were mixed with *Staph aureus* and added to human blood. Until some years ago there was on the experimental side little evidence that phage had an *in vivo* antibacterial action, except for a few observations suggesting that phages injected into an animal simultaneously with such organisms as *Salm. typhi* or *Bact. coli* had a slight protective action (Wollman 1925, Arnold and Weiss 1926, Walker 1929). For reports of successful use of phage in the treatment of typhoid fever, see Desranleau (1948) and Dhayagude and Banker (1949).

Thus there was a general failure to demonstrate any protective or curative action of phage filtrates against *Salm. typhi-murium* or *Salm. enteritidis* when tested in mice (Topley and Wilson 1925, Topley *et al.* 1925, Levy 1925, Wollman 1925, Richet and Hauduroy 1925, Bronfenbrenner and Korb 1925-26, Ebert and Peretz 1929, Greenwood *et al.* 1936). Similarly, phage filtrates had little or no protective or curative action in salmonella infections in fowls (Pyle 1926), in experimental plague in rats (Compton 1928, Hale 1931). Nor was there any experimental evidence that the presence of phages in the intestines of mice of a phage acting on *Salm. typhi-murium* prevents the spread of natural contact

suggested in 1914¹¹ and in recent years this relationship has been definitely established.¹² These bacteria produce a soluble toxic substance, or *enterotoxin*, which gives rise to typical food poisoning symptoms in man and rhesus monkeys upon feeding and in kittens upon injection. There is considerable doubt as to the specificity of the kitten test, however, for it has been shown that the staphylolysins will cause vomiting on injection into these animals.¹³ The incubation period in man is short—two to six hours—and the case fatality nil, with complete recovery in twenty-four to forty-eight hours. The nature of the enterotoxic substance is unknown, although its formation by staphylococci appears to be favored by the presence of starch. A period of incubation is necessary for its elaboration by the bacteria, and in outbreaks of this type of food poisoning it is always found that a period of time, generally not less than eight hours, has elapsed between the preparation and the consumption of the food. This type of food poisoning is quite common and a number of well authenticated outbreaks have been reported.¹⁴

Whether or not bacteria other than the staphylococci form similar enterotoxic substances is open to question. The fact that the same incubation period and clinical symptoms are observed when epidemiological evidence incriminates the other bacteria noted above suggests that enterotoxin may be formed by them. Streptococci are occasionally incriminated in food poisoning outbreaks with evidence of enterotoxin formation,¹⁵ and *Bacterium aerogenes*, *Proteus* and similar organisms have been found under much the same circumstances. There is some experimental evidence¹⁶ indicating that the ability to form substances irritating to the human alimentary tract may be one that is possessed by a variety of bacteria, but as yet this is not definitely established.

Food-Borne Bacterial Infections. The food-borne bacteria infections are of two general types. The one consists of those diseases which are transmitted by a variety of vectors of which food is but one and whose clinical symptoms are not those usually associated with food poisoning. Such, for example, are typhoid and paratyphoid fevers, dysentery, cholera and other enteric infections. The second type of infection is that with bacteria of the *Salmonella* group, in which the incubation period is short, the gastro-intestinal disturbance is of short duration, a day or two, and the symptoms are typical of food poisoning. There is some crossing between the two types, for paratyphoid B bacilli (*Salmonella paratyphi* B) may produce either the typical food poisoning response or paratyphoid fever.

The first group ordinarily comprises the so-called "residual typhoid," for example, which remains in spite of hygienic measures. The second group, on the other hand, is the first group ordinarily food-borne and, to a lesser extent, water-borne. The second group, on the other hand, plays an important part in maintaining some of these diseases in endemic form.

induced by the action of phage, but they appeared to have little virulence. On the other hand, strains of *Salm. typhi-murium*, isolated from mice that had died of infection in spite of the presence of phage in the tissues, proved just as sensitive to that phage as the bacteria originally inoculated (Topley and Wilson 1925, Topley *et al.* 1925, Greenwood *et al.* 1936).

Blood, serum, bile, white cells, tissue debris can all inhibit lytic action of phage

may be (see Zdansky 1921) that the cells or colloids of the body fluid exert *in vivo* an inhibiting effect on phage lysis similar to the inhibition exerted *in vitro* by high concentrations of gelatin or agar (Bail 1922, Doerr and Berger 1922, Otto and Munter 1923, Bronfenbrenner and Korb 1925). This suggestion is supported by the observation that some of the most hopeful results of bacteriophage therapy have been obtained in cholera—a disease in which the infecting vibrios are multiplying freely in the watery contents of the intestine.

In any case, until we know more than we do of the factors that prevent any but high concentrations of phage from exerting any protective effect in the tissues, we cannot justifiably conclude that it is impossible so to adjust the conditions that a large part of the *in vitro* activity might be made available for therapy in the infected animal.

SUMMARY

(1) There is no doubt that variations in diet are associated with variations in resistance to infective diseases. Starvation to the point of inanition, resulting either from lack of protein or calorie in the diet, or from a low food intake following loss of appetite due to depletion of certain vitamins, decreases both non-specific resistance and the capacity to synthesize antibodies; and lesser degrees of malnutrition probably have a similar though lesser effect.

(2) Depletion of protein is clearly a cause of lowered resistance. Depletion of Vitamin A, especially in the period of rapid bodily growth, is associated with a lowered resistance, but there is no good evidence that depletion of Vitamin D has any significant effect on resistance. Quite apart from any accompanying general malnutrition, depletion of several of the water-soluble vitamins—those of the B-complex, and Vitamin C—decreases resistance and antibody formation.

There is no reason to suppose that the dietary factors which affect resistance are confined to the known vitamins.

Whether a given depletion is effective in this respect depends on the species of host and of parasite, and the tissue responses characterizing the particular infection. This dependence is strikingly illustrated in certain virus infections, in which a depletion apparently increases the host's resistance; presumably because virus multiplication depends on active tissue metabolism.

(3) There is no consistently good evidence that any food factor in excess of normal requirements enhances resistance to infections.

(4) The experimental evidence with regard to the influence of fatigue on resistance suggests that it is more important as a factor leading to the activation of a latent infection than as predisposing to infection *ab initio*.

(5) The data with regard to the effect of variations in the physical environment are scanty. It is certain that fluctuations in temperature and humidity

control of water and milk supplies is, in large part, food-borne. The employment of cooks and other food handlers who are typhoid carriers provides the opportunity for food infection and consequent transmission of the disease. Mary Mallon—"Typhoid Mary"—was one of the most notorious examples of a cook who was a typhoid carrier.

Of the *Salmonella* infections, one of three species is generally involved, *Salmonella typhi-murium* (*S. aertrycke*) and its varieties (*newport*, *stanley*, etc.), *Salmonella enteritidis* and *Salmonella cholerae-suis* (including *Voldagsen* and *paratyphi C*). *S. typhi-murium* is the most frequently observed, while *S. cholerae-suis* is only rarely present. The ingestion of food containing large numbers of these organisms frequently results in the typical symptoms of food poisoning. No enterotoxin substance has been shown to be formed by these bacteria, and it is probable that actual infection takes place as indicated by the somewhat longer incubation period and the finding of the bacteria in the feces. The case fatality is variable, ranging from zero to 10 per cent. Almost any kind of food may serve to carry these microorganisms, although meats and other protein foods predominate. This type of food poisoning is not common.¹⁷

Both *S. typhi-murium* and *S. enteritidis* are commonly carried by rats and mice, and it is probable that in many cases these rodents are responsible for the infection of food. In others the source of infection may be a human carrier, and in many cases of meat poisoning it has been found that the meat was from a diseased animal.

Shellfish and Disease. Shellfish, including oysters, clams and mussels, have been responsible for the transmission of enteric disease, especially typhoid fever, through pollution of areas in which they are grown or stored. They are commonly eaten in an uncooked or partially cooked condition which facilitates transmission of disease; it has been found that, while scalloped oysters, fried clams and clams in chowder are practically sterilized, steamed clams, fried oysters, oysters in stew and mussels cooked in the usual ways are not freed from coliform bacteria. The shellfish, in the course of breathing and feeding, filter large quantities of water and readily take up enteric pathogens from polluted beds or when placed in brackish waters near sewage outfalls to "fatten." Imbibed bacteria, if not ejected very soon, are passed through the gastro-intestinal tract and discharged in about five hours. In the warm season the pollution of the water of a bed or storage area is highly correlated with infection of

rapidity with which bacteria are passed through shellfish suggests the possibility that they may be cleansed of infection by storage in clean or even chlorinated water. The possibility is not only feasible but practiced, four days sufficing to practically eliminate all coliform bacteria. Essentially the same methods that are used for the bacteriological examination of water (p. 253) are applied to shellfish. The United States Public Health Service has suggested that not more than 50 per cent of the 1 ml. samples of pooled shell liquor and finely chopped tissue of 10 or more oysters, clams or mussels should show

coliform bacteria in the presumptive test but the figure is a guide rather than a standard and is not inflexible.

The food-borne parasitic infections include the various flukes, tapeworms, echinococcus and round worms that infect man. In these diseases the infective stage of the parasite is often present in a food substance as a consequence of its life cycle and the mechanisms involved may be found elsewhere (See Chapter 34.)

IMMUNITY—ANTIGENS, ANTIBODIES AND THE ANTIGEN-ANTIBODY REACTION¹

It has been common knowledge for many years that recovery from certain of the infectious diseases is accompanied by the development of an enhanced resistance, and second attacks of a disease once overcome are not common. This enhanced resistance, or immunity, is specific, *i.e.*, an individual immune to one disease may be no more than ordinarily resistant to others, and is *variable from one disease to another, some giving rise to a "solid" immunity of long duration while in others the immunity is imperfect or partial and transient.* The specific immune state supplements the complex of factors which make up non-specific resistance to infection, and in some instances even a solid immunity may be broken down by fatigue, malnutrition and similar factors which are not consistent with a state of physiological well-being. Immunity arises as a consequence of the reaction of the host to intimate contact with the parasite, or its products, within the tissues, and constitutes a last line of defense whose presence frequently prevents infection and whose development during an attack of disease determines the outcome. The reaction of the host to the invading microorganism has been studied intensively since the early days of bacteriology, and the body of knowledge so accumulated makes up the extraordinarily complex science of immunology. These studies have not only led to some degree of understanding of the phenomenon of specific resistance to infection but in addition have provided biology with a new method whose general application has been, thus far, limited.

ANTIGENS

An antigen is ordinarily but unsatisfactorily defined as any substance whose introduction into the tissues of an animal results in the appearance, after a suitable length of time, of antibodies in the blood serum and other body

¹ Much of the earlier work on immunity and related problems will be found in the following volumes: Ehrlich, *Gesammelte Arbeiten zur Immunitätsforschung*, Berlin 1904, 1908, 1910, 1912, 1914, 1916, 1918, 1920, 1922, 1924, 1926, 1928, 1930, 1932, 1934, 1936, 1938, 1940, 1942, 1944, 1946, 1948, 1950, 1952, 1954, 1956, 1958, 1960, 1962, 1964, 1966, 1968, 1970, 1972, 1974, 1976, 1978, 1980, 1982, 1984, 1986, 1988, 1990, 1992, 1994, 1996, 1998, 2000, 2002, 2004, 2006, 2008, 2010, 2012, 2014, 2016, 2018, 2020, 2022, 2024, 2026, 2028, 2030, 2032, 2034, 2036, 2038, 2040, 2042, 2044, 2046, 2048, fluids. With certain exceptions, the reaction is *specific* in that each antigen stimulates the formation of antibody for itself and no other antigen, and it takes place only when the antigen is a *foreign substance* to the animal into which it is injected. This characterization is of course, one that is based on what antigens do rather than what they are, for knowledge of the nature of these substances is as yet too fragmentary to permit a general definition in terms of composition and configuration of the chemical compounds which exhibit the property of antigenicity.

In general, antigenic substances are proteins, and probably all naturally occurring proteins soluble in the body fluids and containing a full complement of amino acids (the so-called complete proteins) may function as antigens. According to Wells² the presence of aromatic radicals is associated with antigenicity, proteins deficient in aliphatic amino acids but containing aromatic amino acids, such as zein, gliadin, egg albumin and casein, are antigenic, while gelatin and protamines which are deficient in aromatic radicals are not antigenic. The property of antigenicity is not destroyed by heating except as the protein is rendered insoluble by coagulation (specificity is somewhat altered), but it is lost upon hydrolysis, probably at a very early stage, although the precise point at which antigenicity disappears during hydrolytic cleavage of the molecule is not known. Antigenicity, then, appears to be a property of the intact, or nearly intact, protein molecule, and there is reason to believe that one prerequisite of antigenicity is a large molecule which may exist in colloidal solution.

Iso-antigens. It is not strictly true that antibody response is induced only by antigens foreign to the inoculated animal unless the term foreign is taken to mean not present in the circulation of that animal. It was early observed by Hektoen³ that thyroglobulin would act as an antigen in the same species of animal from which the tissue was taken, and since then it has been found that lactating goats will produce antibody to their own casein and that lens protein is antigenic even in the same individual animal. It has long been known, too, that the serum of the viper will protect against the venom of that snake as efficiently as the best hyperimmune horse serum. It is definitely established, therefore, that an animal will produce antibody against certain antigens occurring and their corresponding certain types of an general, iso-antibody titers are low.

The Human Blood Groups.⁴ It was discovered by Landsteiner⁵ that human blood could be divided into four immunological groups which represent the four possible combinations of two antigens present in the erythrocyte. The serum contains antibody (agglutinin) for the absent antigens, antigen and corresponding antibody do not coexist in the same blood. There are three systems of nomenclature for these groups (see table) of which the International

is by far the most widely used. Additional immunological factors are also known to be present and are responsible for a part of the observed transfusion incompatibilities; these can be avoided if donor and recipient blood are tested against one another as well as typed. These blood groups are inherited by Mendelian law and for this reason are of considerable interest in connection with the question of normal antibodies (p. 329) as well as having some forensic utility in cases of disputed paternity, etc. Blood groups occur in lower animals as well as in man, as in the rat⁶ and in cattle.⁷

The Specificity of Antigens. Closely associated with the nature of antigens is the specificity of the immunological reactions. Not only does a given antigen stimulate the formation of a specific antibody but it will react, either *in vivo* or *in vitro*, only with its own antibody or antibodies to closely related antigens. For example, the serum proteins of the higher animals, while highly specific for species, show cross reactions with the antibodies to the serum proteins of closely related species; human blood serum shows no immunological relationship to horse or rabbit serum but reacts to some degree with antisera prepared against the serum proteins of anthropoid apes and certain monkeys.⁸ Immunological differences between individuals of a single species are, of course, found in the human blood groups. The inheritance of blood groups and the correspondence of immunological relationships of species with generally

accepted zoological classifications are indicative of the fundamental significance of antigenic specificity.⁹

It should be noted, however, that, although the great majority of antigenic substances are species-specific, certain antigens are found to occur in distantly related organisms. Of these the more important are lens protein (actually two proteins, α and β crystallin), which is common to a wide variety of animals, and an antigen known as Forssman antigen, heterophile antigen or, less frequently, heterogenetic antigen. Heterophile antigen has been found in the organs of the guinea pig, horse, cat, dog, mouse, chicken, turtle and several

virus invariably resulted in a frank case of the disease, diagnosable by ordinary clinical methods, it has become increasingly clear of late years that atypical, abortive, and latent infections are very common and play an important part in the genesis of naturally acquired immunity. Even in so highly contagious a disease as measles, there is evidence to show that *not every susceptible child who is exposed to infection contracts the disease.*

Stocks (1928, 1930*a, b*), in a series of careful analyses of the relevant data, showed that the morbidity figures for measles, for chicken-pox and for German measles are inexplicable except on the assumption of immunization in the absence of diagnosed disease, or of an effective inherited immunity. That the former factor is operative can be demonstrated by comparing, during any epidemic prevalence, the attack rate among children who have previously been intimately exposed to risk without contracting the disease with that among children who have previously been less intimately exposed. The natural history of these widely prevalent virus diseases, as developed by Stocks, presents striking analogies to the natural history of diphtheria or of scarlet fever.

In other virus diseases the occurrence of atypical cases and of healthy carriers has obtained general recognition. Wickman (1907), for example, pointed out that it was impossible to account for the epidemiological behaviour of poliomyelitis without assuming the existence of latent and atypical infections; and Stocks (1932), examining the figures of a series of outbreaks, calculated that the ratio of those developing latent immunizing infections to those developing clinical attacks of the disease was probably of the order of 100 to 1 or more. The same ratio was reached by Howe (1949) in the United States of America.

These estimates, based on epidemiological data, have been largely corroborated by the finding of neutralizing antibodies in the general population

Aycock and Kramer (1930*a, b, c*), using the highly susceptible monkey as a test animal, determined the protective power of samples of serum obtained from convalescent cases and from normal persons. Some 90 per cent. of the former and just over 50 per cent. of the latter showed protective antibodies in the serum. Similar tests were later carried out on normal persons, giving no history of poliomyelitis, living in another area of the United States. Of 21 adults, 18 showed neutralizing antibodies in their blood. Brodie (1932) recorded analogous findings in Montreal. In endemic areas infection occurs at a very early age. Hammon (1949), for instance, working on the Pacific island of Guam, was able to demonstrate the presence of neutralizing antibodies in infants during their first year of life, usually in the complete absence of apparent illness.

If we accept the view that the presence of such antibodies indicates previous contact with the virus of poliomyelitis we can hardly escape the corollary that mild atypical attacks, or a purely immunizing carrier infection, must be an exceedingly common event in this particular disease. This conclusion is borne out by the finding of the virus in the throat or faeces of a varying proportion of family contacts of cases of poliomyelitis, and of non-contacts during epidemic periods (see Kling *et al* 1912, Flexner *et al* 1913, Kling and Pettersson 1914, Flexner and Amoss 1919, Lépine *et al* 1939, Brown *et al* 1948, Howe 1949, Hammon 1949, Casey *et al* 1950). From the distribution of the virus in the child population of Chicago, Casey, Fishbein, Schabel and Smith (1950) estimated that most children had been infected at least once by their 4th birthday, and 75 per cent. twice by their 6th birthday.

Yellow fever is another disease in which latent infections appear to be very common. Serum protection tests in South America and West Africa have shown that in endemic areas, where clinical cases are infrequent and sporadic, a high

species of fish, in some bacteria, such as certain of the paratyphoid and dysentery bacilli and pneumococci, and in some varieties of maize. It is not present in the erythrocytes of any of these animals but is present in the red cells of the sheep, whose organs do not contain it. It is not found in other organisms such as the pig, ox, rabbit, goose, frog, eel, man, pigeon and rat. This peculiar distribution among species has not been explained.

Still other antigens which are common to, or closely related in, widely different species are those which confer organ specificity. Possibly the immunologically related caseins may be considered in this category but, further, antigens present in a given organ such as kidney are similar to those in the same organ of a different species. These have been studied in some detail by Witebsky.¹⁰ The so called heavy proteins, isolated from disintegrated normal tissue by ultracentrifugation and thought by some to represent mitochondria, have been of interest in connection with the isolation of similar material from virus infected tissues which is believed to represent the infectious agent. Immunological studies on these substances by Furth and Kabat,¹¹ and by Henle, Chambers and Groupe,¹² have indicated that heavy proteins from various organs show three kinds of immunological specificity, namely, species specificity or immunological relation to other organs of the same animal, organ specificity, or immunological relation to the same organ of other species, and, finally, specificity for the organ of the one species. Similarly, Bailey and his co-workers¹³ have reported finding organ specificity in nutrient media which was derived from the tissues used for the preparation of the infusion. It has been reported by some that organ-specific antisera are specifically toxic for that organ, i.e., nephrotoxic, etc., but the evidence is not altogether unequivocal.

A number of antigens are common to different species of bacteria or to bacteria and certain other organisms and will be discussed in the following chapter in connection with natural immunity.

The Chemical Basis of Specificity.¹⁴ A large body of sound experimental evidence has established the fact that the specificity of antigens is determined by their chemical composition. Early experimental investigation of a wide variety of antigenic proteins has shown that immunologically identical proteins are, so far as can be determined, identical in composition; that antigenic proteins differing from one another in composition are also immunologically distinct, and that antigens showing some degree of cross reaction are closely related in chemical structure. Conclusive evidence that immunological specificity is a property of certain atomic and molecular arrangements has, however, been obtained through the study of altered specificity and artificial antigens.

The specificity of an antigenic protein may be altered by heating, partial denaturation, treatment with formaldehyde, etc., in such a way that part of the original specificity is lost but species specificity remains although somewhat

to remain latent in the tissues unless the equilibrium is upset. *Group 2.* Immunity persists but the virus does not. Examples are smallpox, chicken-pox, measles, yellow fever, and the insect-borne encephalitides. *Group 3.* Neither infection nor immunity persists. Influenza, the common cold, and foot-and-mouth disease are typical instances. *Group 4.* Both infection and immunity persist indefinitely, as in the transmissible tumours. The varying part played by active and passive immunity in these different groups will become evident during the course of this chapter.

The Mechanism of Virus Infections.

The general process of tissue invasion in virus diseases does not appear to differ in any essential way from that of bacterial infections. There would seem, in many diseases at least, to be the same sequence of local proliferation, blood-stream invasion and secondary foci of infection, each phase varying in prominence according to the virulence of the virus and the susceptibility or resistance of the host.

Thus, Todd and White (1914) note that, when cattle are injected subcutaneously with a small dose of the virus of rinderpest, the blood usually remains non-infective for 72 hours, becoming infective coincidently with the onset of illness: and Andrews and others (Report 1931) report that the virus of foot-and-mouth disease does not appear in the blood of experimentally infected cattle until shortly before the commencement of the febrile reaction, though it may be present in high concentration some hours before the temperature begins to rise, or before vesicles appear. The virus then tends to persist in the blood throughout the febrile period, though the degree and persistence of blood-stream infection varies widely in different animals (see also Waldmann, Trautwein and Pyl 1931). In yellow fever, Hudson and Philip (1929) find that monkeys bitten by infected mosquitoes show the presence of virus in their blood 1 to 2 days after infection, and at about the same interval before the onset of fever.

In many diseases characterized by a skin eruption the infecting virus can be shown to be widely distributed throughout the body. Even in vaccinia, in which the obvious lesions are commonly restricted to the site of inoculation into the skin, a viraemia may be present (Ohtawara 1922, Rivers and Tillett 1923, Gildemeister and Heuer 1927), and, with highly potent strains, this may lead to a widespread eruption and to lesions in the internal organs (Douglas, Smith and Price 1929).

The careful studies of Fenner (1949a) on mouse-pox (ectromelia) and of Downie (1951) on smallpox reveal a picture not unlike that of experimental mouse-typhoid infection (see p 2125).

After gaining access to the body, the virus produces a small primary lesion at the site of lodgment, passes to the lymphatic nodes and thence to the blood stream, where it causes a primary viraemia. Progressive infection occurs of cells in the internal organs till, towards the end of the incubation period, the virus overflows into the blood stream producing a secondary viraemia. At the beginning of the clinical disease pocks appear on the skin, and antibody becomes detectable a few days later.

In diseases affecting the nervous system, such as poliomyelitis and encephalitis, it used to be thought that the virus remained strictly confined to the nervous tissues, gaining access to the central nervous system by way of the axis cylinders and diffusing by neural pathways through the brain and cord. Improved technical methods, however, have shown that, even in these diseases, a transient viraemia may occur. In the insect-borne encephalitides the virus appears to reach the nervous system from the blood stream, and in poliomyelitis it apparently enters the blood from its site of primary lodgment before the central nervous system is obviously affected (see Chapter 87). Experimental observations on poliomyelitis

methods and something of their nature is known. The polysaccharide haptens referred to above are of very considerable immunological importance in many, but not all, cases. The isolation of such substances is relatively simple, usually involving a primary alcohol precipitation from solution of the bacterial cell substance. The somatic antigens of the enteric bacilli, which appear to be identical with endotoxin in many cases, may be prepared by extraction of the intact cells with M/2 trichloroacetic acid in the cold,²³ by extraction of the intact cells with glycols such as diethylene glycol,²⁴ by fractionation of tryptic digests of the cells,²⁵ or by dissociation and extraction in 6 M urea.²⁶ These substances may be precipitated from the crude extract by alcohol and further purified. Though it has been indicated earlier that these substances are polysaccharide-lipid complexes, there is not complete agreement on this point. Preparations made by primary trichloroacetic acid extraction do appear to be of this nature but those isolated by glycol extraction are polysaccharide-lipid-polypeptide complexes. These may be dissociated and reconstituted in hot formamide solution and the polypeptide portion seems to be essential to antigenicity. Sharp separation of the immunological specificity of the flagellar antigens has not been possible by chemical means, but physical separation in which the flagella are broken off by shaking and separated from the cell proper by differential centrifugation has been accomplished. The flagellar antigen is a protein in nature. In the "protein" separated from the flagella

The immunological entities have not been separated in such preparations, however.

The number of antigens that can enter into this mosaic in a single species is unknown, some *Salmonella* species have been found to contain seven or eight separate antigens which differ from one another not only immunologically but also in their resistance to heat, alcohol and the like, and these and other bacteria will undoubtedly prove to be increasingly complex with further study. The number of antigens demonstrable by antigenic analysis (p 300) is, of course, only a minimum since a given antigen remains an entity only so long as possible components of it have not been found to occur separately. It is of some interest that antigens co-existing in the same cell may not be equally demonstrable. The species specificity observable in rough pneumococci, for example, is present in the smooth forms but is masked by the predominant type-specific antigens. Similar phenomena have been observed in a variety of bacterial species. Conversion to varying degrees of roughness may bring to light "new" antigens which, though presumably constantly present, have been masked by the presence of other antigenic substances. There is a tendency to interpret such findings as indicating the relative position of antigenic substances within the cell, the peeling off of "outer" antigenic layers and exposure of secondary and tertiary layers of antigen within the cell. While there is something to be said for this concept as a figurative mode of expression, it may be pointed out that, aside from the fact that in some bacteria specific antigen is

to suggest that endotoxins, similar to those contained in certain bacteria, may be produced by viruses. Rake and Jones (1944), for example, found that the lymphogranuloma, meningopneumonitis, and mouse pneumonitis viruses (see Chapter 85), when grown in the yolk sac of the developing chick embryo, elaborated a thermolabile endotoxin capable on intravenous inoculation into mice of causing death in 4 to 24 hours (see also Manire and Meyer 1950). A similar toxic effect on mice, independent of multiplication of the virus, was observed by Henle and Henle (1916) after intracerebral inoculation of the virus of influenza. The development of tissue-culture techniques has shown that many viruses have a cytopathogenic effect, causing degeneration and death of the cells in which they are multiplying. How far this is due to toxic action and how far to interference with the metabolism of the cells by competitive growth is not yet clear. In Burnet's (1950) view the symptoms exhibited by patients suffering from virus diseases are due not to toxins but to soluble products derived from cell damage.

In one instance, at least, namely the action of the influenza virus on the red cell, the so-called toxin can almost certainly be identified with an enzyme. The phenomenon of *haemagglutination* is described in Chapter 74 but, briefly, it is found that the influenza virus is able to agglutinate the red blood corpuscles of fowls and certain animals. It probably does this by becoming adsorbed on to the cells and forming a bridge between them. If the virus-cell mixture is kept at 37° C for a time, the virus, which is at first removed by the cells from the fluid, sooner or later begins to reappear. Simultaneously the cells cease to be agglutinated, and remain inagglutinable even by fresh virus, though the eluted virus itself is able to agglutinate fresh red cells. The experimental evidence suggests that the virus secretes an enzyme of the mucinase class which acts on a mucopolysaccharide receptor in the cell. Much the same process occurs in the lung, except that, instead of being released from the cell, the virus enters and multiplies within it (see Hirst 1943, Burnet 1950). The *haemagglutinating* effect of the influenza virus can be neutralized non-specifically by certain lipid substances present in normal serum as well as specifically by influenzal antiserum. Numerous other viruses are known to cause *haemagglutination* under appropriate conditions, though the mechanism by which they produce this effect is not always the same. In vaccinia, for example, the *haemagglutinin* is not the virus itself, but a soluble product of it, containing a phospholipid component which is responsible for union with the surface of the red cell and which is destroyed by the *lecithinase* of *Cl. welchii* Type A—an enzyme that has no effect on *haemagglutination* by the influenza virus (Burnet 1946).

Besides a *haemagglutinating* action, a few viruses such as the virus of mumps and of Newcastle disease of fowls, are able to lyse the red cells of certain animals. Like the *haemagglutinin*, the *haemolysin* can be adsorbed on to red blood corpuscles and its action neutralized by specific antiserum, though the two enzymes differ in their heat stability and in other ways (see Morgan *et al* 1948, Chu and Morgan 1950).

Antiviral Immunity.

Before discussing the mechanism of antiviral immunity it will be convenient to consider briefly the ways in which such immunity may be induced; since it is held by many that, in this respect, there is a significant difference between the behaviour of the filtrable viruses and bacterial cells.

Active Antiviral Immunity.—We have seen that active immunity is conferred

present in the capsule or flagella, there is no evidence of an immunological geography in the bacterial cell.

The demonstration of the occurrence of common antigens in heterologous bacteria may be interpreted in two ways. Thus it may be assumed that the identical antigen, or at least its determinant portion, is shared. This is a common view and one for which there is a good deal of justification in many instances. It is believed by some, however, that the observed cross reactions are attributable to the occurrence of similar determinant groups and the type of partial antigen-antibody reaction observed with artificial antigens. As yet there is no definitive evidence to substantiate either view.

ANTIBODIES

The immunological response of an animal to the initial injection of an antigenic substance is not immediate but after a suitable time interval or incubation period is manifested as an alteration in the properties of the blood serum with respect to the antigen. An immune serum, or antiserum, differs from normal serum in that it reacts, either *in vivo* or *in vitro*, with the homologous antigen. This property of immune serum is a consequence of the presence of *antibodies*, substances which are formed by the animal body in response to the presence of antigen in the tissues, and which combine specifically with the antigen. The antigen-antibody reaction is demonstrable in a number of ways, the particular technique employed depending upon the nature of the antigen. By such means five apparently different kinds of antibodies may be found, although, as will appear, these are probably but a single substance. They are as follows:

- (1) the *antitoxins*—antibodies formed in response to the injection of toxins which, when mixed with the homologous toxin, neutralize its poisonous qualities,
- (2) the *lysins*—antibodies which bring about a dissolution or lysis of bacterial and other cells;
- (3) the *opsonins*—antibodies which sensitize bacterial cells in such a way that they are readily engulfed by the phagocytic cells,
- (4) the *agglutinins*—antibodies formed in response to the injection of bacterial cell substance which, when mixed with the homologous microorganism, immobilize the bacteria if they are motile, then aggregate, or agglutinate, the cells with the formation of clumps which settle out of suspension;
- (5) the *precipitins*—antibodies formed in response to the injection of antigens which, when mixed with soluble antigen, aggregate the molecules with the formation of a precipitate.

In addition to these five generally recognized kinds of antibodies, two others may be provisionally added:

- (6) *ablastins*—reproduction inhibiting antibodies which prevent the multiplication (cell division) of the invading microorganism.
- (7) *neutralizing antibodies*—antibodies which, when mixed and incubated with the infectious agent, generally a filterable virus, render it non-infective.

The various antibodies may be considered briefly one by one.

(d) By means of inactivated viruses. Numerous methods are employed for the process of inactivation. Drying was used by Pasteur in the preparation of his rabbit-cord virus against rabies (incidentally this method, like many others under this heading, is a combination of *c* and *d*); formalization by Curasson and Delpy (1926) and Daubney (1928) for cattle plague, by Laidlaw and Dunkin (1928*a, b*) for distemper, and in combination with heat for foot-and-mouth disease by Waldmann and his colleagues (1941-2); phenolization by Semple (1912) for rabies and by Todd (1928*b*) for fowl plague, crystal violet for swine fever (see Doyle and Wright 1917); and ultraviolet irradiation for rabies, St. Louis encephalitis and other virus diseases (Levinson *et al.* 1945). Sometimes the immunizing effect is increased by adsorbing the inactivated virus on to alum, as in Waldmann's vaccine against foot-and-mouth disease (Waldmann *et al.* 1941-2); sometimes an adjuvant is added, such as the mineral oil mixture used by Salk, Bailey and Laurent (1952) for influenza vaccine.

The degree of protection afforded by inactivated vaccines varies considerably, and it is sometimes necessary or desirable to reinforce their immunizing action by subsequent injections of living virus. The process of inactivation is not always easy to control, and with many vaccines a point is soon reached when not only the virulence but the antigenic potency of the virus is destroyed. If the processing is insufficient, then living active virus may survive, as happened with Kolmer's ricinoleate vaccine against poliomyelitis (see Chapter 87): if the processing is too thorough, then the vaccine may be practically devoid of immunizing power.

Whether an inactivated virus is a dead virus is very difficult to decide. A great deal of ambiguous evidence might be analysed without enabling us to arrive at a firm conclusion. Moreover, since the same agent in the same concentration may vary in its effect on two different viruses, it would be impossible to discuss this subject satisfactorily without reviewing the studies on a great number of viruses inactivated in different ways.

W. Henle and G. Henle (1947) found that the various activities of the influenza virus were affected at different rates by ultraviolet irradiation. The properties were affected in the following order: (1) ability to propagate, (2) toxic action as tested by intravenous inoculation of white mice, (3) ability to elicit the interference phenomenon (see p. 1430) and to inhibit the development of the chick embryo; (4) haemagglutinating capacity; and (5) complement-fixing activity. The immunizing power began to decrease before the haemagglutinating power fell, but was still appreciable after all the haemagglutinating power had been lost.

There is plenty of evidence to show that many inactivated vaccines in which no living virus can be demonstrated by any available means are good immunizing agents, and this is really as far as we can go. To attempt to pass beyond this is to enter the realm of metaphysical speculation and to face the difficulty of defining the meaning of live and dead in relation to small particles of biologically active material (see Chapter 41).

Passive Antiviral Immunity.—Turning to passive immunity, enough has already been said to indicate that antiviral sera are at least as effective in affording protection against the homologous virus as is an antibacterial serum in protecting against the homologous bacterium. It may be noted that, though antibacterial sera are commonly prepared by the immunization of some conveniently large animal, usually the horse it has become the practice to prepare antiviral sera by the

Antitoxins. It was found by von Behring and Kitasato²⁷ in 1890 that the immunity of rabbits and mice which had been immunized against tetanus was associated with the ability of the blood serum to neutralize the toxic substances produced by the tetanus bacillus. The substance in the serum which neutralized the tetanus toxin was designated by these workers as *antitoxin*. Subsequent investigation has shown that the animal body forms antitoxins in response to the injection of a variety of antigenic poisons, not only those of bacterial origin such as diphtheria toxin, botulinus toxin and the like, but also against the phytotoxins and zootoxins (p. 206).

The action of antitoxin may be directly demonstrated in the following way: if a fatal, or many times fatal, dose of toxin be mixed with an appropriate amount of antitoxic serum *in vitro*, the injection of the mixture into a susceptible animal is wholly without injurious effect; the poisonous qualities of the toxin are nullified by the immune serum. The reaction is, like all other immunological reactions, highly specific, and an antitoxin which neutralizes the homologous toxin is without effect on heterologous toxins. The nature of the effect of the antitoxin which renders a powerful toxin pharmacologically inert is unknown.

The Toxin-Antitoxin Reaction. The combination of toxin and antitoxin does not necessitate the complete destruction of either component; neutral mixtures of toxin and antitoxin may be dissociated by treatment with hydrochloric acid, by freezing in the presence of phenol or tricesol and, to some extent, by simple dilution. In certain cases, *e.g.*, pyocyaneus toxin and certain snake venoms, in which the toxin is more resistant to heat than the antitoxin, the latter may be selectively destroyed and the neutral mixture becomes toxic upon judicious heating. It appears, therefore, that a more or less loose combination of toxin and antitoxin takes place, the poisonous properties of the toxin being held in abeyance as long as the union persists. The rate of reaction between toxin and antitoxin, like the chemical reactions, is dependent upon temperature, concentration, character of the medium in which the reaction occurs, and similar factors. The avidity of an antitoxin for its corresponding toxin differs in different cases; the union between tetanus toxin and antitoxin, for example, takes place less rapidly than that between diphtheria toxin and antitoxin.

An understanding of the precise character of the toxin-antitoxin reaction is dependent upon the interpretation of phenomena revealed by quantitative studies. It might be expected that a given quantity of antitoxin would always neutralize a constant amount of toxin, that the neutralization would follow the law of multiple proportions. This is, however, not the case, and it appears that the amount of antitoxin required to neutralize a given quantity of toxin is dependent upon (a) the manner in which the two are mixed with one another and (b) the relation between toxicity and combining power in the particular filtrate under consideration.

✓ In the first instance it has been observed that when an excess of toxin is added to its specific antitoxin in several portions at proper intervals of time, much more unneutralized toxin remains in the mixture than if the same quantity of toxin had been added to the same quantity of antitoxin at one time. This is known as the *Danysz phenomenon*. If, on the other hand, antitoxin be

²⁷ von Behring and Kitasato. Deut. med. Wchnschr., 1890, 16 1113.

From the work of Salaman (1937) it seems clear that the neutralizing antibody to vaccinia becomes fixed to the virus particles themselves. Absorption with elementary bodies, but not with the soluble specific substance that takes part in the complement-fixation and precipitation tests, removed the virus-neutralizing bodies from a serum. The observations recorded above suggest that the neutralizing antibody does not lead directly to the death of the virus; and the finding of virus and antibody together in the circulating blood or in growing tissue cultures in vaccinia (Smith 1929), ectromelia (Downie and McGaughey 1935), and psittacosis (Bedson 1937) is additional evidence in favour of this view. The experiments of Andrewes (1929*a, b*) on Virus III and of Rivers, Haagen and Muckenfuss (1929*a, b*) on vaccinia and herpes show that in tissue cultures the formation of characteristic inclusion bodies can be prevented by the addition of immune serum to the cultures before the virus. This may be interpreted as meaning that the antibody interferes with the penetration of the cell by the virus, or that it so alters the virus as to prevent its multiplication when it reaches the interior of the cell.

As with the antibodies acting on bacteria and their products, the antibodies in antiviral sera appear to be confined to the globulin fractions. The early observations of Hartley (1914) on antiserum to cattle plague, of Henseval (1919) and Ledingham, Morgan and Petrie (1931) on vaccinal antiserum, of Matland and Burbury (1927) on antiserum to foot-and-mouth disease, of Weyer, Park and Banzhaf (1929) and Morgan and Fairbrother (1930) on poliomyelitis antiserum, and of Laidlaw and Dunkin (1931) on distemper antiserum—all pointed to the close association of antibody with the serum globulin. There was some disagreement on the particular fraction of the globulin—*α*-globulin or pseudoglobulin—which was most active; but the more recent work of Cohn in the United States of America and of Kekwick in this country leaves little doubt that the neutralizing antibody is concentrated mainly in the gamma globulin fraction (see Chapter 88).

Non-specific Inactivating Agents.—Working with influenza virus Burnet and McCrea (1916) observed that normal ferret sera had quite a strong inhibitory action on hæmagglutination and on the development of the virus both in eggs and in mice. Ginsberg and Horsfall (1949*b*), like numerous other workers, extended this observation to the sera of man, rabbits, guinea-pigs and mice, and showed that the heat-labile component of the serum which was responsible for inhibiting hæmagglutination also neutralized the infectivity not only of the influenza virus but of the Newcastle disease and the mumps viruses as well. Though the component was destroyed by heating to 56° C., there was no suggestion that it was the same as complement, because it did not act in conjunction with antibody, as complement does. It seems probable that the inhibitory component is of lipid nature.

Francis (1947*b*) showed that many apparently normal sera contain a substance which inhibits hæmagglutination by killed influenza B virus but not by living virus. Thus the apparent antibody titre of a serum may be much higher against killed than against living virus—an effect referred to as the *Francis phenomenon* (see Chapter 74).

Another non-specific inactivating agent, of more limited scope, is found in certain polysaccharides. Green and Woolley (1947) noticed that apple pectin, gum acacia, and flaxseed mucilage inhibited the agglutination of chicken red cells by influenza A virus, and that apple pectin interfered with the multiplication of the virus in fertile eggs. Ginsberg, Goebel and Horsfall (1948) showed that the polysaccharide extracted from Friedlander's bacillus inhibited the growth of mumps virus in the allantoic sac of the chick embryo. As little as 5 µgm. was effective. The growth

added to toxin in successive equal portions, it may be shown that, in general, the first portion of antitoxin neutralizes a greater portion of the toxin than the second, the second a greater than the third, etc. In the second case it has been found that there is no constant relationship between toxicity and combining power of a toxic filtrate; toxicity slowly diminishes upon storage but

Such altered toxin, which retains its antigenicity unchanged in addition to its combining powers, is designated as *toxoid* and, when prepared by treatment with formaldehyde, *formol toxoid* or *anatoxin*. The proportions of toxin and toxoid in a given filtrate are variable. Consequently there is no fixed relation between toxicity and power to combine with antitoxin; the MLD's neutralized by a unit quantity of antitoxin may vary from one filtrate to another or in the same filtrate at different times from 30 to 130.

Three theoretical explanations of the toxin-antitoxin reaction have been advanced. They are known by the names of their proponents, Ehrlich Arrhenius and Madsen, and Bordet and Landsteiner.

According to Ehrlich the reaction is purely chemical and essentially similar to the neutralization of a strong acid by a strong base. The combining properties of toxin and antitoxin would, therefore, be a manifestation of primary valencies. This concept is, however, not compatible with the observed behavior of toxin and antitoxin in mixture, the Danysz phenomenon, for instance, suggests that if the neutralization proceeds according to Ehrlich, the reacting substances are not homogeneous but consist of mixtures of substances with varying affinities for one another. On the basis of his studies on diphtheria toxin, Ehrlich postulated a series of components of toxin which differed from one another both in their avidity for antitoxin and in their toxicity.

Arrhenius and Madsen preferred to regard the toxin-antitoxin combination as essentially weak acid by a weak

is attractive in a toxin-antitoxin reaction. Simple dilution of a neutral mixture, for example, does not result in the degree of dissociation that this theory calls for. As a consequence of this and certain other discrepancies, the theory of Arrhenius and Madsen, is, like the theory of Ehrlich, not generally accepted at the present time.

A third concept, proposed by Bordet and strongly supported by Landsteiner, is that of the toxin-antitoxin reaction as an *adsorption phenomenon*, essentially physico-chemical in nature and arising as a consequence of intermolecular forces (secondary valencies). The varying degrees of toxicity apparent in the neutralization of toxin may be regarded as due to differences in completion of saturation of the individual toxic units, a process that may be compared to certain staining reactions such as the action of iodine upon starch, a dilute iodine solution producing a light blue tinge, a stronger solution a deep blue. This adsorption theory would view the action of antitoxin upon toxin as a sort of progressive attenuation, proportional to the amount of antitoxin added. The evidence for such a mechanism, not only in the toxin-

ovaries among the females. Thus we find the highest frequencies in those tissues for which vaccinia virus is known to have a special affinity and in those organs—lungs, liver, spleen and adrenals—which are primarily concerned in freeing the blood stream from inanimate foreign particles or from bacteria.

According to Flexner and Amoss (1914), the injection of poliomyelitis virus into the veins of monkeys—a route that does not commonly lead to the production of the typical disease—is followed by the prompt deposition of the virus in the spleen and bone marrow, but not in the kidneys. Galloway (Report 1931) recorded a few experiments in which the infectivity of various organs was determined 24–48 hours after the injection of foot-and-mouth virus into the pad of the guinea-pig's foot. The concentration of virus was highest in the blood; the spleen, liver and lungs contained virus in detectable amount, though the mesenteric glands, ovary, testis and muscles did not. In dog distemper (Laidlaw and Dunkin 1928*a, b*), organs rich in reticulo-endothelial cells, such as the spleen, show a high virus content. Valuable observations on the distribution of the mouse-pox virus in the tissues of experimentally infected animals at different stages of the disease were made by Fenner (1949*a*), whose series of papers will well repay study.

A review of the available data appears to justify the following conclusions. Where the virus concerned has an affinity for some special tissue in which it causes its characteristic lesions, it will, naturally enough, be found in the greatest concentration in those lesions or in their immediate neighbourhood. Thus we find vaccinia virus in the highest concentration in the lymph of the pustules, the virus of foot-and-mouth disease in the fluid of the vesicles, the virus of rabies, or of poliomyelitis, or of Borna disease, in the central nervous system, and so on; but even in these diseases the other tissues in which the virus is most frequently present, if we except the blood, are those concerned in the normal clearing mechanism—the spleen, liver, lungs, bone marrow or adrenals. In generalized infections, in which localization in the skin or nervous system is not a feature of the disease, the reticulo-endothelial tissues frequently show the highest virus content.

The blood we must consider in rather more detail. That the virus may often be demonstrated in blood withdrawn during the febrile stage of illness, or even at other times, we have already seen; but many of the results recorded, particularly in the later stages of experimental infections, have been curiously irregular. It would appear that these irregularities have been due in part to the fact that the virus is often present in the cellular elements—particularly in the leucocytes—rather than in the plasma, and that viricidal antibodies may appear in the plasma, while virus is present in the cells.

As long ago as 1899 Kolle showed that the infective agent in the citrated blood of an animal suffering from cattle plague was readily removed by centrifugation. The supernatant plasma was non-infective; the deposit, containing the blood cells, infective to a high degree. Todd and White (1914) studied this phenomenon in greater detail and showed that the virus was mainly associated with the leucocytes, and Schein (1917) and Daubney (1928) recorded similar findings. Russ (1906) (see also Landsteiner and Russ 1906) found that the virus of fowl plague was present in greater amount in the cellular constituents of the blood than in the plasma, and Todd (1928*a*) showed that the concentration was highest in the leucocytic layer, though Doerr and Gold (1932) recorded experiments which they interpreted as indicating an adsorption of the virus by the red cells.

Smith (1929) made a careful study of this problem in experimental vaccinia in the rabbit. Comparing the infectivity of the whole blood, the plasma, and the washed deposit of cells during the early days of a generalized infection he found that the washed cells were most infective, and the plasma non-infective. By fractional centrifugation it was possible to show that the red cells played no part in fixing the virus. The results suggested

antitoxin reaction but in antigen-antibody reactions in general, is very strong indeed, and it is generally regarded as highly probable that these reactions are essentially physico-chemical in nature. This view of the immunological reactions will be considered at greater length in a later section.

The Standardization of Antitoxins. The quantitative evaluation of the toxin-neutralizing capacity of antitoxic sera is clearly a matter of considerable practical as well as theoretical importance. Ehrlich originally proposed as the standard unit of diphtheria antitoxin that amount which would just neutralize 100 guinea pig MLD's of toxin. As indicated above, however, variability in the relation of toxicity to combining power invalidates any standard based on toxicity; in other words, the combining power of a toxin is not a measure of its toxic qualities. On the other hand, since the combining power of a toxic filtrate remains constant within narrow limits, it is possible to establish an arbitrary standard unit upon which the relative strength of all antitoxic sera can be based. Such a standard diphtheria antitoxin was first prepared by Ehrlich and was preserved by him with all precautions against possible deterioration. A standard antitoxic serum based on Ehrlich's arbitrary standard unit is also prepared in this country by the National Institute of Health of the United States Public Health Service, and is distributed every two months to the licensed producers of commercial serum. The unit is international, standard sera being tested from time to time by the Biological Standardization Commission of the League of Nations.²⁸

Three methods are used in the titration of diphtheria toxin and antitoxin. The first of these is the classic method of Ehrlich in which two limits (Lat., *limes*) are determined by guinea pig inoculation. These are the L_0 dose of toxin, which is defined as the standard unit of antitoxin, and the L_+ when mixed with one unit of standard antitoxin. The L_0 dose of toxin is the amount which produces a 100 per cent mortality in the inoculated guinea pigs is considered to contain one unit of diphtheria antitoxin.

A second method is based upon the observation that the intradermal injection of 1/250 to 1/500 MLD of diphtheria toxin into a guinea pig is followed by a local reaction, swelling and erythema and, with slightly larger amounts of toxin, necrosis, a phenomenon sometimes called the *Romer reaction*. By the use of such intradermal inoculations an L_r dose of toxin may be determined, i.e., that amount of toxin which, when mixed with one standard unit of antitoxin, will produce the minimal skin reaction. The serum to be standardized is mixed in varying amounts with L_r doses of toxin, and that amount of serum which gives the minimal skin reaction is considered to contain one unit of antitoxin.²⁹ This method has the advantage of allowing the testing of a number of toxin-antitoxin mixtures in one animal but has not displaced the classic method in common usage.

The third method makes use of the Ramon flocculation, the *in vitro* precipita-

²⁹ Glenny and Allen: Jour. Path. and Bact., 1921, 24:61

be understood that, when we use the term "cells" in relation to viruses, we are generally referring not to the reticulo-endothelial cells of the body, which are so active in antibacterial immunity, but to the particular cells invaded by the virus. The reticulo-endothelial system, as we have just seen, undoubtedly acts in conjunction with neutralizing antibodies to dispose of certain types of virus; but when we speak of cellular immunity in virus diseases we have in mind an entirely different mechanism, namely the resistance of normally susceptible cells to invasion by active virus particles. We know that neutralizing antibodies, if mixed with virus before inoculation, or if injected into an animal before the virus, are capable under suitable conditions of preventing infection. Even, however, in virus infections in which a strong neutralizing antibody can be obtained the available evidence suggests that inactivation of the virus can occur only extracellularly. Once the virus has penetrated the cell, it seems to be adequately shielded from the antibody. When, as in the prophylaxis of measles, the antibody reaches the majority of the susceptible cells before the virus, the virus may be neutralized either on the surface of the cell or in its immediate vicinity; but if the serum is given too late, after the virus has penetrated the cells, it is almost or completely without effect. Again in smallpox, as Downie (1951) showed, neutralizing antibody developing within a few days of the onset of the disease has no power to prevent the maturation of the skin lesions, because the virus is already protected by virtue of its intracellular position. In fact, patients may die in the pustular stage of the disease having a high titre of antibody in the serum, in much the same way as a horse used for the production of antiserum against tetanus will die if the toxin is injected directly into the brain where it is inaccessible to the serum antibody (For further studies on the protective effect of the cell on viruses, see Perdrau and Todd 1936)

Though neutralizing antibodies, if appearing naturally during the course of the disease or given artificially after the cells have become infected, may be unable to hinder the development of the lesions, there is good reason to believe that the degree of immunity after recovery is closely related to the persistence of these antibodies. As Beveridge (1952) points out, the diseases belonging to Francis' Group 2 (see p. 1415), such as smallpox, yellow fever and the insect-borne encephalitides, are systemic diseases characterized by the development of neutralizing antibodies which persist in the circulation, often for years. Another feature of this group of diseases is that they are caused by only one antigenic type of virus. Francis' Group 3, on the other hand, comprises diseases such as (a) influenza, poliomyelitis and foot-and-mouth disease, in which there is more than one antigenic type of virus, so that neutralizing antibodies developed against one type do not protect against infection with a different type, and (b) herpes febrilis in which the lesions are restricted largely to the surface of a mucous membrane where there is little neutralizing antibody available. In neither of these groups is there any need for predicated the existence of a specific cellular immunity to explain the freedom or otherwise from second attacks.

What about Francis' Group 1, however, of which psittacosis and lymphogranuloma are the outstanding examples? In these diseases the virus often persists in the tissues for a long time, recrudescences may occur at intervals, and no lasting immunity develops. It is significant that in this group neutralizing antibodies, except perhaps in very low titre, cannot be demonstrated. Why this should be so, it is impossible to say, but it may be remarked that these viruses are among

tion of toxin and antitoxin when mixed in optimal proportions.³⁰ Standard antitoxin is mixed with varying quantities of toxin, and the tube first, i.e., in time, showing precipitation contains one Lf dose of toxin. Varying amounts of the serum to be standardized are mixed with the Lf dose of toxin. The amount of serum in the tube first showing flocculation in this second series is considered to contain one unit of antitoxin. This method differs from the other two in that it depends upon the combining power of a toxic filtrate rather than on toxicity. It is generally used, not as a final method of standardization, but as a preliminary to standardization by the Ehrlich method.

The interrelationships of these limits are of some interest. The L+ dose is, of course, larger than the L₀ dose, and, because of the peculiarities of the toxin-antitoxin reaction, by considerably more than one MLD. The Lr dose approximates the L₀ dose as might be expected in view of the small amount of toxin required to elicit the skin reaction. The Lf dose is generally somewhat less than any of these, since it is a measure of combining power rather than toxicity and is unaffected by differences in the proportions of toxin and toxoid. It would appear that the Lf/Lr ratio should be the same for a given toxic filtrate immediately upon standardization. It has been found, however, that this ratio differs with different antitoxic sera. This appears to be a consequence of differences in avidity, not of hypothetical toxin components as suggested by Ehrlich, but of antibody. The avidity of antitoxic sera is associated with the protein fraction containing the antibody; successive globulin fractions differ from one another in avidity (see also p. 314).

The Bactericidal Substances—Lysins. It was early shown by Nuttall³¹ that fresh, defibrinated animal blood is markedly bactericidal. This property, also possessed by cell-free serum, was found to be heat-labile and destroyed by holding at a temperature of 55° to 56° C. for thirty minutes. Such heated sera are said to be *inactivated*. The blood or serum from a single animal species is not equally active on all species of bacteria and, conversely, a given bacterial species is affected to varying degrees by the blood of different animal species. It was suggested by Buchner that the natural resistance of an animal to infection could be explained in part by this bactericidal quality of the blood, and he proposed the name *alexin* (Gr., to ward off) for the heat-labile activity.

Although this bactericidal activity of the blood and serum of normal animals is frequently specifically increased by immunization, such an increase does not invariably accompany the development of the immune state. The serum of guinea pigs immunized with *Vibrio metchnikovii* is strongly germicidal for that microorganism, while that of unimmunized guinea pigs is devoid of specific bactericidal quality. On the other hand, immunization with streptococci, while producing a specific resistance to infection with the bacterium, frequently fails to induce an increased, specific germicidal activity.

Pfeiffer Phenomenon. The bactericidal effect is, in some instances, accompanied by visible dissolution of the bacterial cells. The course of events following the introduction of cholera vibrios into the peritoneal cavity of an immunized animal was followed microscopically by Pfeiffer³² and described by

³⁰ Ramon. *Compt. Rend. Soc. Biol.*, 1922, 86 661, 711, 813.

antibody response to a non-specific stimulus was recorded by Horsfall and Curnen (1946) in mice latently infected with the pneumonitis virus and injected intranasally with a suspension of normal chick embryo.

Interference Phenomenon.—Though most of the phenomena of immunity in virus diseases can be explained on the basis of humoral antibodies, experimental observations in the laboratory, made first by Hoskins (1935) and later by Findlay and MacCallum (1937) and a host of other workers, have shown that a form of cellular resistance may be induced by certain special procedures. It was found that monkeys inoculated with a pantropic strain of yellow fever virus died; but that if neurotropic virus, which is not normally fatal, was injected at the same time, the animals survived. Since the precocious development of antibodies seemed to be ruled out, the explanation offered was that the neurotropic variant occupied a proportion of the cells that would normally have been invaded by the pantropic virus and so prevented them from being infected by this fatal form of the virus.

Numerous other examples of this interference phenomenon, as it is now called, might be quoted. References will be found in the review by Henle (1950). In some instances the phenomenon can be reproduced by an attenuated virus, as in the protection of dogs against distemper by the injection of a distemperoid virus (Green and Stulberg 1946); sometimes by another virus of the same group, as in the inhibition of growth of the psittacosis virus in the fertile egg by previous injection of the virus of meningo-pneumonitis (Golub and Wagner 1948); sometimes by another virus of a different group, as in the ability of a non-neurotropic influenza virus injected intracerebrally to protect mice against subsequent infection with the virus of Western equine encephalomyelitis (Vilches and Hirst 1947); and sometimes by the same virus after inactivation (see Isaacs and Edney 1950). In some instances the protecting virus has to be injected into the same tissue as the test virus: in others the two viruses may be injected into different tissues. The interference phenomenon may likewise be called upon to explain the difficulty of demonstrating by infectivity tests small numbers of living virus particles in the presence of large quantities of dead virus (Andrewes and Elford 1947).

Immunity of this type, in which a cell already occupied by a virus is resistant to infection by other particles of the same or nearly related virus, may perhaps be referred to as *pre-emptive immunity*—a term suggested by Dr. C. H. Andrewes. We know that such an immunity occurs in plants and in the developing chick embryo, in which humoral antibodies have never yet been demonstrated; and there is increasing evidence that it plays a part in the defence of the host against some of the animal virus infections. It must be made clear, however, that the phenomenon occurs only under special conditions and that it is by no means universal.

Syvertson and Berry (1947), for example, working with virus-induced tumours, were able to infect cells with two viruses at the same time. Thus the cornea of the rabbit could be infected simultaneously with vaccinia and with herpes virus, as shown by the presence of cytoplasmic and intranuclear inclusion bodies in the same cells. Incidentally, as the authors point out, the isolation of a given virus from a tissue or tumour does not necessarily prove that this virus was responsible for the lesions observed.

The mechanism of the interference phenomenon in virus infection is clearly independent of any specific response of the host cell to the antigens of the blocking virus, since the blocking and the blocked virus are in many instances antigenically

him in detail. The vibrios first lose their motility, then swell up and crumble into small fragments. The dissolution of the fragments follows, and no trace of the bacterial cell remains visible. This action of the body fluids is attributable to the presence of an antibody termed a *lysin* (Gr., to loose, dissolve). It occurs not only within the peritoneal cavity of an immunized animal, but also when the peritoneal fluid or blood serum is removed from the body and brought immediately in contact with the bacteria *in vitro*. The lytic activity of bactericidal sera *in vitro* is heat-labile and the process of lysis appears to be essentially identical with that observed *in vivo*.

Visible lysis of bacterial cells, however, does not invariably accompany the lethal activity of a bactericidal serum. In fact, the majority of bacteria are not dissolved by immune sera in the manner described above. This is not to be taken to indicate that the processes are fundamentally different; not only are many bacteria highly resistant to visible structural alterations, viz., the lack of sensitivity to wide variations in osmotic pressure, mechanical pressure, etc., but, as will appear, the antigen-antibody reaction takes place in two stages, the first the union of antigen and antibody and the second the visible consequences of that union. Whether or not dissolution of the bacterial cells occurs, it may be readily shown that they unite with the lysins.

Hemolysis. The lysis of bacteria by an immune serum is not a unique reaction in which only bacterial cells may play a part; bacteriolysis is, rather, a special case of a general phenomenon, for immunization with a variety of cells results in the production of cytolytic sera. Of these, erythrocytes have been by far the most widely studied, for the lysis of these cells, hemolysis, is readily apparent in the test tube; the red opacity of the cell suspension changes to the clear red solution of hemoglobin as lysis proceeds. The stroma is not dissolved but, upon examination, appears misshapen. First demonstrated by Bordet,³³ hemolysis has been particularly useful not only as a type of lytic reaction peculiarly suitable for laboratory manipulation, but also as an indicator of antigen-antibody combination when visible lysis does not or cannot take place. It may be noted that the immune hemolysins, i.e., those formed by the animal body in response to the injection of erythrocytes, are to be distinguished from the filterable hemolysins formed by bacteria (p. 206).

Antisera have been prepared against a variety of other cells. The injection of spermatozoa leads to the appearance, in the serum of the inoculated animal, of a spermatotoxic substance that first renders the corresponding spermatozoa motionless and then kills them. A number of similar cytolytic sera have been prepared—"nephrotoxic" sera by the injection of kidney cells, "hepatotoxic" sera by the injection of liver cells, etc., but the organ specificity claimed for these last has not been satisfactorily demonstrated.

The Mechanism of the Lytic Reaction. An observation contributing in large measure to a partial understanding of the mechanism of the action of the immune lysin was that lytic or bactericidal activity could be completely restored to an inactivated serum by the addition of a small amount of fresh unheated serum, either normal or immune. It appears, therefore, that the

³³ Bordet: Ann Inst. Pasteur, 1898, 12:688.

after infection. It had no direct action on the two viruses *in vitro*, and did not affect their absorption by the host tissues; and it did not affect the influenza and Newcastle viruses. The presumption that it blocked a metabolic system in the host cell which was used only by the pneumonitis and mumps viruses was borne out by the demonstration of interference of the pneumonitis by the mumps virus and of no interference of influenza or Newcastle disease viruses by mumps or pneumonitis virus, and *vice versa*. The influenza and Newcastle disease viruses, which interfered reciprocally with one another, evidently depend in common on a single metabolic system in the host cells that is insusceptible to the Friedländer polysaccharide (Horsfall and McCarty 1947, Ginsberg *et al.* 1948, Ginsberg and Horsfall 1949a).

Closely allied to the interference phenomenon is what Beveridge (1950) called the *excessive dose effect*. Many instances can be quoted of virus diseases in which a small dose of living virus gives rise to a severer reaction than a large dose. For a discussion of the possible explanation of this effect, reference should be made to Beveridge's article.

Allergy in Virus Diseases.

The characteristic response to reinoculation with vaccinia virus affords one of the classical examples of an allergic reaction. The typical sequence of events after a successful primary inoculation commences with an incubation period lasting about 3 days, followed by the appearance of papules at the sites of inoculation on about the 4th day. These develop into compound vesicles during the next 5 days, become definitely pustular about the 10th day, and heal by the well-known scabbing process between the 14th and 21st days. If a person who has been successfully vaccinated is again injected with calf lymph during the period of waning immunity, but before he has again become fully susceptible, the most noticeable feature in the local reaction is an acceleration of all stages. The papules appear earlier, sometimes within 24 hours; and vesiculation and pustulation, when they occur, are in evidence at a far earlier period than after primary vaccination. Very frequently, however, the reaction ceases at the papular stage, and this may be so transitory as to be missed unless daily examinations are made. In any case, the induration round the papules or vesicles is usually far less marked after a secondary than after a primary vaccination, and the constitutional symptoms are slighter. We have, in fact, the typical allergic combination of accelerated response with localization of infection. It is known that in previously vaccinated persons the so-called immediate reaction, reaching its maximum within 72 hours, can be produced by heated vaccine as well as by live vaccine (see Andervont and Rosenau 1930, Broom 1947), whereas it does not occur in unvaccinated persons unless they have suffered from smallpox. There is reason, therefore, to regard it as an allergic response. An increased reactivity of the skin to injection with live or inactivated virus can be demonstrated in persons or animals that have recovered from a variety of other virus diseases, such as psittacosis, lymphogranuloma, influenza, mumps, and swine fever.

In general, the more recent the infection, the stronger is the degree of allergy. This fact leads to the question whether allergy is merely an indicator of immunity, or is actually an integral part of it. Without entering into a discussion of this topic here (see pp. 1331 and 1522), it may be remarked that Beveridge (1952) would regard the allergic condition as part and parcel of immunity. In his view

lytic reaction is a consequence of the interaction of three components, rather than two as in the case of the toxin-antitoxin reaction. One of these is clearly an immune body, *i.e.*, is formed in response to the injection of the antigen, and another, the heat-labile component present in normal as well as immune serum. The third component is, of course, the antigen.

The heat-labile component was termed alexin by Buchner,³¹ as indicated above, and renamed *complement* by Ehrlich. The immune body or antibody was called *substance sensibilisatrice* or *sensitizer* by Bordet and *amboceptor* by Ehrlich. The relation between these components may be expressed in tabular form for a hemolytic system

erythrocytes (antigen)	+	unheated immune serum (complement or alexin + amboceptor or sensi- tizer)	=	hemolysis		
erythrocytes (antigen)	+	heated immune serum (amboceptor or sensiti- zer)	=	no hemolysis		
erythrocytes (antigen)	+	heated immune serum (amboceptor or sensi- tizer)	+	unheated normal serum (complement or alexin)	=	hemolysis

These components react with one another, not at random but in an orderly manner; the union between antigen and amboceptor must precede the reaction with complement. Complement does not combine with antigen in the absence of amboceptor, but antigen and amboceptor will unite regardless of the presence of complement. This may be demonstrated directly by using mixtures of only two components or in the presence of all three by holding the mixture at 0° C.; the antigen-amboceptor union readily takes place at this temperature, but complement unites only slowly and may be demonstrated in the supernatant following centrifugation.

According to Ehrlich, complement acts upon the antigen only indirectly through the amboceptor, the last functioning as a bridge between the first two. In this connection it is of interest that colloidal silicic acid may act as a sensitizing agent in the lysis of red cells. The evidence does not require that the action of complement be indirect in this way; it is established only that the antigen must be sensitized by the antibody before union with complement can occur. According to Bordet the union is in the nature of a specific adsorption, the sensitized antigen being rendered susceptible to the lytic action of the complement. For example, it is well known that tannic acid will act as a sensitizer, and treated erythrocytes are lysed in the presence of complement. The evidence, which cannot be considered at length here, strongly supports this view. In consequence it is generally admitted that the terms alexin and sensitizer are preferable to complement and amboceptor, although the latter remain in common usage. Quantitative studies by Heidelberger and his co-workers³² have shown that under ordinary circumstances

³¹ Buchner originally used the term alexin to designate the entire bactericidal action of the blood serum, alexin was later used by Bordet for the heat labile substance alone; and at the present time alexin is regarded as synonymous with complement.

³² Heidelberger Jour. Exp. Med., 1941, 73-681. Heidelberger, Weil and Treffers, *ibid.*, 1941, 73-695. Heidelberger, Rocha e Silva and Mayer: *ibid.*, 1941, 74-359.

in deciding whether tonsillectomy predisposes to an attack of the disease or merely to the bulbar form of it, but doubtless suitable studies will show before long which is correct.

Numerous observations are on record to show that paralysis may follow shortly after certain prophylactic injections, particularly of vaccines such as combined diphtheria and pertussis vaccine alum precipitated. Paralysis usually develops within 3 weeks and affects first of all the injected limb. Here again, whether the vaccine predisposes to an attack of poliomyelitis or merely to the localization of paralysis at the site of injection is not clear, though the evidence points towards the former (see McCloskey 1950, Hill and Knowelden 1950).

The effect of nutrition on altering resistance to virus infection is very imperfectly understood. The general impression that infantile paralysis picks out the healthiest and best fed children may have nothing to do with nutrition as such, but may be associated with the hygienic conditions which tend to prevent the better housed social classes from suffering from latent or subclinical infections at an early age. The part played by various nutritional deficiencies was summarized in an article by Findlay (1948), which deals also with the effect of other non-specific factors on resistance to virus disease. (See also p. 1374.)

An interesting example of activation of the virus of mouse hepatitis by *Eperythrozoon muris* is recorded by Andrewes and his colleagues. So far none of the viruses with the exception of those of the lymphogranuloma-psittacosis group, have proved amenable to treatment with chemotherapeutic or antibiotic agents (see Hurst 1953).

Useful reviews, which have been freely drawn on in the writing of this chapter, have been published by Bedson (1937), Burnet, Keogh and Lush (1937), Andrewes (1939, 1952), Rivers (1943), Francis (1947a), Fenner (1949a), Hammon (1949), Downie (1951), Beveridge (1952), and Wilson Smith (1953).

SUMMARY

It is perhaps a fair summary of the evidence presented in this chapter to suggest that it is compatible with the view that there is no essential difference between the mechanisms concerned in antiviral and antibacterial immunity. It would appear that neutralizing antibodies play a greater part and phagocytosis a smaller part in the defence of the body against viruses than against bacteria. In so far as immunity to virus infections is more effective than immunity to bacterial invasion, the difference may be due rather to the greater limitations imposed on the virus by its habit of intracellular parasitism than to any special reaction on the part of the host.

about seven molecules of complement are required for each molecule of antibody, but in very dilute solution the ratio may approach unity. These workers believe that complement exists in a loose union with antibody but is tightly bound in the antigen-antibody complex.

The Neisser-Wechsberg Phenomenon (Complement Deviation). It was observed by Neisser and Wechsberg that when varying amounts of immune serum (amboceptor) are added to constant amounts of normal serum (complement) and antigen, there is, as might be expected, no lysis with very small amounts of amboceptor, but as larger amounts are added, lysis takes place. When, however, amboceptor is added in considerable excess, lysis again fails to take place. From these and similar experiments it was concluded that a "deviation of complement" occurs under conditions where the amboceptor is in great excess, i.e., the complement unites with the unbound amboceptor rather than with the amboceptor which has united with the antigen. A special explanation need not be devised for this phenomenon, however, for a similar failure of antigen-antibody union to occur is apparent in other serological reactions in the region of antigen or antibody excess. Such, for example, is the prozone phenomenon (p. 301) in the precipitin and agglutination tests. The same effect may be observed *in vivo*, for successful protection of mice against pneumococcus infection has long been known to be dependent upon optimal amounts of antiserum and culture; otherwise a zonal phenomenon in which there is no protection (the *Schwellenwert* of Neufeld and Haendel) may be encountered.

The Bordet-Gengou Phenomenon or Complement Fixation. As pointed out above, the lytic action of an immune serum is difficult to observe with many bacteria and cannot take place with an antigen such as egg albumin. Whether or not the phenomenon of lysis occurs or is made evident through some observable change in the antigen, it is possible to demonstrate the union of antigen and antibody by the addition of an indicator system. The lysis of red blood cells is used for this purpose and is commonly referred to in this connection as the hemolytic system; sheep cells and sheep hemolysin are generally used.

The antigen and inactivated serum (either of which may be unknown) are mixed together with the proper amount of complement in the form of fresh, unheated guinea pig serum. If the antigen and the inactivated serum unite, the complement will combine with the sensitized antigen and is said to be "fixed." When the hemolytic system is added in the form of heated hemolytic serum and erythrocytes, no complement is available, hemolysis does not occur, and the test is positive. If, however, the antigen and inactivated serum do not react, the complement remains free and combines with the sensitized red cells, hemolysis results and the test is negative. This phenomenon may be illustrated in the following way:

The quantitative aspects of the test are obviously of primary importance,

chapters. Intelligent interference with the course of events is impossible without a clear idea as to what is actually happening.

We may recognize, in theory, at least six categories of hosts among any infected herd. Four of these categories include individuals who are themselves infected, (1) the typical case, (2) the atypical case, (3) the latent infection, and (4) the healthy carrier; the other two categories are not themselves infected, or infective, (5) the uninfected immune and (6) the uninfected susceptible. The division between (2), (3) and (4) is formal rather than actual—these conditions shade into each other by imperceptible degrees. It is doubtful whether the division between (3) and (4) is justifiable even for convenience of description, since many, perhaps most, of the class commonly described as healthy carriers are in reality suffering from a symptomless, and often negligible, infection. It may be noted that the individuals falling in categories (3) and (4) are in general, though in a very varying degree, resistant to further infection from without; so that the only fully susceptible hosts at risk are those in class 6.

Fig. 271 may help the student to visualize the kind of distribution, both of infection and of immunity, that may be met with in infected herds under different epidemic conditions. No distinction has been made in the diagram between latent infections and healthy carriers. A few arrows have been introduced to indicate the direction of effective spread—effective in the sense of producing new cases of disease or in converting susceptibles to immunes. As we shall see, an epidemic of an infective disease is usually accompanied by an epidemic of symptomless immunization.

In this figure, A may be taken as an example of an epidemic phase in an endemic-epidemic prevalence, that is, as representing the state of affairs during an outbreak of an infective disease from which the affected herd is never completely free, epidemics of varying severity recurring at more or less frequent intervals. B may be regarded as a later stage of A, or as a small epidemic wave occurring in a herd in which susceptibles are few, while carriers are frequent. C may be taken as representing the state of affairs during a severe epidemic occurring in a herd with little initial immunity. An extreme example of this catastrophic type of prevalence has occasionally been afforded by the introduction of such a disease as measles into an isolated island community that has either never experienced the infection before, or has been free from it for many years. D may be regarded as representing a stage of relative quiescence between two outbreaks of the type depicted in A. It will be noted that the proportion of susceptibles is higher than in A or B, and with such a distribution as this a fresh outbreak of the A type is likely to occur.

Herd Immunity in Diphtheria.

As an illustration of the types of distribution depicted in A, B and D, no better example could be selected than that of diphtheria. We are here dealing with a disease that is essentially a toxæmia; and, as we have seen, an effective antitoxic immunity will in this case protect the host against clinically detectable infection. In the Schick test we have a method which allows us to divide the members of any herd into susceptibles and immunes. Except in the case of very young children a negative reaction may be taken as an indication that an individual has something over 0.01 A.U. of antitoxin per ml. of circulating blood, and also that he will produce further antitoxin briskly and effectively in response to any entry of toxin

and each reagent must be titrated and added in the proper amount. As usually carried out, the degree of hemolysis is estimated as O, +, ++, +++ or ++++, the last representing complete hemolysis. A considerably more accurate end point is that of 50 per cent hemolysis, measured in a photoelectric colorimeter or spectrophotometer. A quantitative complement fixation which allows a close approximation of amount of antibody has been developed,³⁶ in which an excess of complement is added to the antigen-antibody mixture and the amount remaining after fixation titrated with the usual hemolytic system to a 50 per cent end point.

The complement-fixation test may be used with a known antiserum for the identification of an unknown bacterium or with a known antigen as a means to detect antibodies in an unknown serum. Perhaps the commonest application of the test is in the diagnosis of syphilis, where it is known as the Wassermann test.

*The Nature of Complement.*³⁷ It is likely that the process of lysis is accomplished by complement, the antibody simply sensitizing the antigen to this lytic action. Complement is not increased during immunization, and a higher titer immune serum may be only feebly lytic because there is not sufficient complement present to utilize the excess of amboceptor. It is of some interest that there is little species specificity in complement; that from guinea pig serum, for example, may bring about the lysis of beef corpuscles in the presence of amboceptor in goat serum. Some quantitative differences are apparent, however, for a serum which may be actively complementary in some reactions may be relatively inactive in other combinations.

The property of inactivation by heat has been referred to above. Complement is also inactivated by shaking, but in neither case is the inactivation completely irreversible, for some activity may be regained on standing. In this respect complement behaves as a typical hydrophilic colloid which can be made to aggregate by physical forces but shows a tendency to spontaneous dispersion and restoration to the original state. The activity disappears upon standing—rapidly at room temperature (two or three hours) and more slowly in the ice-box, where it may be preserved for three or four days. Complement is irreversibly destroyed by strong acids or alkalis and reversibly inactivated by ions such as Mg, Ca, Ba, Sr and SO₄ or by hypertonic salt solutions. In this connection it is of some interest that complement which is inactivated by raising the salt concentration to 5 to 10 per cent may be preserved at low temperatures in this form for several weeks, the activity being regained upon dilution with distilled water. These properties and some others, such as ready adsorption on surfaces, suggest a close relationship between complement and the enzymes; it has also been pointed out that there are remarkable resemblances to certain compounds of protein with soaps and lipids. An association of complement with the blood-clotting mechanism is suggested by the observations that many substances have both anticoagulant and anticomplementary activity, and that there is a close correlation between thromboplastic and complement-fixing power of tissue ex-

³⁶ Mayer, Osler, Bier and Heidelberger: *Jour. Immunol.*, 1948, 59, 195.

³⁷ See the review by Pillermer. *Chem. Rev.*, 1943, 33 1.

of events in any particular community that is vastly more informative than we can at the moment supply for most other diseases.

It has of course long been recognized that the diphtheria bacillus is not confined to those who are suffering from the clinical disease in its typical form. It is frequently isolated from cases of mild sore throat associated with an epidemic of typical diphtheria, less frequently from healthy contacts, and still less frequently from non-contacts.

Kober (1899) records the isolation of diphtheria bacilli from 70 per cent. of 139 contacts who were themselves suffering from mild sore throat, and from 8 per cent. of 123 contacts who had apparently normal throats. Closeness and continuity of contact, here as in other diseases, have a considerable influence on the carrier rate. The collected figures recorded in the Medical Research Council's monograph on diphtheria (see Monograph 1923) show a 15 per cent. carrier rate of virulent diphtheria bacilli among 610 contacts in barracks or hospital wards, a 7 per cent. carrier rate among 10,883 home contacts, and a 0.6 per cent. carrier rate among the general non-contact population.

As a measure of the risk to which an ordinary urban population is submitted we may take the carrier rate of virulent diphtheria bacilli among children attending the elementary schools in and about London. During the third decade of the century it fluctuated between 2.5 per cent. and 5 per cent. (see Dudley 1923, Forbes 1927).

The events that follow the passage of virulent diphtheria bacilli from the throat of a case, or of a carrier, to the throat of a non-infected person will depend on the immunological condition of the recipient. If he is susceptible (Schick-positive) he will either respond by developing antitoxin and so becoming more resistant, and eventually Schick-negative, or else he will develop clinical diphtheria. Hence Schick-positive carriers of virulent diphtheria bacilli are very rare. They are not non-existent—they cannot be if we accept the view that the transition from the susceptible to the immune class is usually the result of latent infection—but we may take it that a person who is carrying virulent bacilli in sufficient number to be detectable by an ordinary swabbing is (a) immune (Schick-negative), or (b) undergoing rapid immunization to the Schick-negative level, or (c) incubating the disease.

If, then, we take the case of a relatively isolated community, such as a large boys' school, and trace the spread of infection and the development of immunity during an epidemic of diphtheria, we shall observe the following sequence of events.

At the start we may suppose that we have 50 to 70 per cent. Schick-negative immunes and 30 to 50 per cent. Schick-positive susceptibles. Among these boys there will be a certain number of carriers of virulent diphtheria bacilli, say 3 per cent.; these will be immunes.

When these bacilli spread to uninfected boys they may obtain lodgment either in a susceptible or in an immune; and, depending on the dose of bacilli transferred, the exact degree of immunity of the recipient and many other factors of which we have as yet no knowledge, they may bring about any of the following transformations.

Frequently:

- (a) Schick-positive susceptible → case (mild or severe).
- (b) Schick-positive susceptible → Schick-negative immune
 - (a) without detectable carrying,
 - (b) with detectable carrying.
- (c) Schick-negative immune → Schick-negative immune carrier.

tracts and sera. It seems clear, however, that complement is not identical with prothrombin, and more recent work³⁸ suggests that inactivation of complement of plasma blocks the conversion of prothrombin to thrombin. The nature of the lytic action of complement is as yet, however, purely speculative.

Complement is intimately associated with the serum proteins and there is reason to believe, viz. the destruction of complement by trypsin and the antigenicity of the activity, that this lytic agent is protein in nature. Complement may be split into two parts by the separation of serum protein into albumin and globulin. The globulin fraction will unite with sensitized cells although no lysis occurs, and is called the *mid-piece*, while the albumin fraction which will not unite with the sensitized antigen in the absence of the mid-piece but produces lysis when it unites with the sensitized cell-mid-piece complex is termed the *end-piece*. Other investigations have indicated that complement may be split up into four components by other fractionation methods. These are:

C_1 or mid-piece which is precipitated from guinea pig serum by passing CO_2 through the serum diluted 1:10 with distilled water, or by dialysis against distilled water. This component is destroyed at $56^\circ C$ in 30 minutes and is a euglobulin containing carbohydrate.

C_2 or end-piece which remains in solution after the C_1 fraction is precipitated. It shows the same heat lability and is a part of a mucoglobulin fraction containing 10 per cent carbohydrate.

C_3 is inactivated by yeast, zymin or cobra venom and is not destroyed at $56^\circ C$ in thirty minutes.

C_4 or fourth component is specifically inactivated by treating guinea pig serum with dilute ammonia, hydrazine or viper venom, or by shaking with chloroform or ether. It is also heat-stable but this stability is greatly reduced in the presence of 10 per cent sodium chloride. It appears to be a carbohydrate portion of the mucoglobulin fraction containing C_2 whose carbonyl groups are attacked by ammonia.

Human complement likewise consists of these four components and they are mutually interchangeable with those in guinea pig serum.³⁹ The four components are also present in frog serum and carp serum and are either identical or closely related to those of guinea pig serum.⁴⁰ The titer of complement is, of course, limited by the fraction occurring in smallest amount; this appears to be C_2 in human serum, and C_3 in guinea pig serum. All four components are necessary for lysis of red cells and bactericidal action, but all are not equally fixed by the antigen-antibody complex. In general, relatively large amounts of C_1 and very small amounts of C_3 are fixed, but the relative fixation depends upon what other components are present.

Opsonins. If a mixture of polymorphonuclear leucocytes and bacteria or other particulate matter is incubated for a time, it will be found on microscopic examination that a number of the leucocytes have ingested the foreign particles. Few if any particles will be ingested if the mixture is prepared in physiological salt solution, a considerable number if the fluid is normal serum. In

well illustrated by the case rates and carrier rates in one group of some 160 boys during the winter term of 1921 and the winter term of 1922.

		Case Rate.	Carrier Rate.
1921	: : : :	7 per cent.	2 per cent.
1922	: : : :	0.6 " "	6 " "

In 1921 during a severe epidemic, following on a period in which the school had been free from diphtheria for 2 years, the spread of virulent bacilli produced 3.5 cases to one carrier; in the winter of 1922 after this severe exposure, and in spite of the entrance of 43 new boys during the post-epidemic period, the spread of infection produced 10 carriers to one case.

In judging the significance of such figures we must remember that the real carrier:case rate over any considerable interval of time is always higher than that given by comparing the recorded case rate with the recorded carrier rate over that period—a point stressed by Dudley (1932). All clinical cases of diphtheria will be recorded. A case rate of 3 per cent. per annum in a particular community means that 3 persons in every hundred of those exposed to risk develop diphtheria during the year in question. But a carrier rate of 7 per cent. does not mean that 7 per cent. become carriers during the year; it means that at any one swabbing of an adequate sample 7 persons in each hundred are, on the average, found to be harbouring diphtheria bacilli. The total number of persons that become carriers during the period in which the three cases of diphtheria occur will be much higher. Thus, over one yearly period, Dudley records an average carrier rate of 6.6 per cent. with small fluctuations above or below this level; but repeated swabbing (7-8 times) of a large sample of boys showed that at least 40 per cent. were harbouring the diphtheria bacillus at one time or another during this period.

The general significance of the picture presented by such studies as these is clear enough; but we must remember that the two categories—immunes and susceptibles—that are divided from one another by simple Schick testing present a very incomplete picture of the graduations in resistance that actually exist in a herd at risk. Glenny (1925) defines five grades of immunity, which are set out in Table 84. These are, of course, not exhaustive; nor are they sharply demarcated from one another (see also Parish and Wright 1933).

TABLE 84

SHOWING VARYING GRADES OF RESISTANCE TO DIPHTHERIA. (After Glenny.)

	Group				
	1	2	3	4	5
Schick test	~	+	+	+	+
Antitoxin in blood . .	> 1/30 A.U.	< 1/30 A.U.	0	0	0
Earlier stimuli . . .	Many	Many	Many	Few	None
Response to further stimuli	Rapid	Rapid	Rapid	Slow	Very slow
Description	Immune	Immune	Potentially immune	Sub-immune	Fully susceptible

If we could elaborate our study of a population at risk by estimating at regular intervals the exact amount of antitoxin in each person's circulating blood; and if, dealing with a very large population, we could withdraw an adequate sample of persons at frequent intervals and determine the response of each Schick-positive person to small injections of toxoid, we should be able to build up a far more detailed picture of what was really happening. Adopting Glenny's classification, we should be able to detect the transformation from the fully susceptible to the sub-immune, and thence through the Schick-positive immune to the fully developed Schick-negative immune, as well as transference from the Schick-positive to the Schick-negative class.

the case of bacteria, great numbers of the microorganisms will be found packed into the leucocytes when the two are suspended in the specific immune serum. The antibodies present in the immune serum which so remarkably stimulate this engulfment by body cells are designated *bacteriotropins*, a term not in common use, or *opsonins*. The term opsonin was originally used to designate the activity of normal serum, hence the antibodies in the immune animal are sometimes called immune opsonins. The cells which ingest such particulate matter are termed *phagocytes* (devouring cells). This property is not confined to the polymorphonuclear leucocytes or heterophils, although these have been most widely used in *in vitro* experiments because of their availability, but is

Fig. 34. Phagocytosis of pneumococci by culture macrophages. 1, Phagocytosis in presence of normal serum, relatively few bacteria have been ingested. 2 and 3, Phagocytosis in the presence of antipneumococcus serum, enormous numbers of pneumococci have been ingested and appear as agglutinated masses. The lightly staining forms are degenerating. Hematoxylin and eosin-azure II. $\times 1200$ (Zuckerman).

also present in various mononuclear phagocytes. These cells and their role in immunity are discussed in the following chapter.

The Opsonic Index. A quantitative estimate of opsonin present in a given immune serum may be made by comparing the number of bacteria ingested by normal leucocytes in normal serum with the number ingested by normal leucocytes in the immune serum. The appropriate mixtures are prepared and incubated in capillary tubes, smears made and stained, and the bacteria engulfed by an arbitrary number (usually 50 or 100) of leucocytes counted.⁴¹ The average number of bacteria per leucocyte, or *phagocytic index*, is determined for the normal and immune sera, and the ratio of the phagocytic index of the immune serum to that of the normal serum is termed the *opsonic index*.

⁴¹ The details of this technique may be found in Wright and Colebrook: *Technique of the Teat and Capillary Glass Tube* 2nd ed. Constable and Co., Ltd., London, 1921; Fleming: *A System of Bacteriology*, Medical Research Council, London, 1931, 9 212.

of the same general kind as that now available in the case of diphtheria; but we have not yet any records comparable in detail and duration with those afforded by Dudley's work at Greenwich. So far as our fragmentary records go they look like pieces of a very similar picture, with one essential difference. The production of the erythrogenic toxin forms a relatively small part of the pathogenic potentialities of hæmolytic streptococci; and an antitoxic immunity that will suffice to prevent the occurrence of the clinical syndrome that we label scarlet fever will not suffice to prevent the spread of tonsillitis, or of other clinically obvious streptococcal infections (see Okell 1932). For effective immunity against all the clinical manifestations of infection with hæmolytic streptococci we need an antibacterial as well as an antitoxic immunity; and this antibacterial immunity will almost certainly be type-specific.

Turning to diseases in which antitoxic immunity, in the strict sense in which we are using that term, plays no apparent part, we are not in a position to give any adequate description of the course of events in a naturally infected herd. This is because we have no such simple tests as the Schick and Dick reactions by which to separate our immunes from our susceptibles. There are good reasons for believing that by an adequate survey, including a careful study of the distribution of the infecting organism and tests for the presence of specific antibodies in the blood of the hosts at risk, we could add greatly to our knowledge of what is happening during an endemic or epidemic prevalence. But we have not got that knowledge yet.

Some things we do know. We know that in certain diseases, such as cerebrospinal meningitis, the ratio of carriers to cases is very high (see for instance Glover 1918), so that it seems probable that the immunes greatly outnumber the susceptibles. The same general relationship—a widespread carrier epidemic associated with relatively few clinical cases—seems to hold in certain virus diseases, such as poliomyelitis and encephalitis lethargica.

In other diseases, such as typhoid fever, the ratio of carriers to cases is not so high (see Chapter 69). But we know that atypical cases of typhoid fever occur during an epidemic, and that many carriers of typhoid bacilli give no history of ever having suffered from a typhoid-like disease. It is a fairly safe assumption that an endemic or epidemic prevalence of typhoid fever is associated with the occurrence of sub-clinical immunizing infections. We know quite certainly that such a prevalence leaves behind it infected healthy carriers who may be a potent source of further spread.

THE EXPERIMENTAL STUDY OF HERD INFECTION AND IMMUNITY

It is clearly possible, by selecting a convenient host species and a parasite that spreads naturally among them, to submit problems of the kind we have considered above to direct experimental study—initiating an epidemic of a particular disease among our test population, and studying the reactions of new entrants, of old members of the herd, or of migrants from one herd to another, by any available means (see Greenwood *et al.* 1936). We can, under such conditions, observe the effects of any intentional interference we choose, splitting a herd into smaller units, reaggregating these units after any selected interval, varying the rate of

The opsonins may be estimated also by the dilution method; specimens are prepared in the usual way, except that the normal and patient's sera are diluted with saline or Ringer's solution. One mixture is made with salt solution or Ringer's solution to determine the degree of spontaneous phagocytosis. The dilution of serum which gives the same amount of phagocytosis as a mixture without serum is taken as the end point.

The Factors Influencing Phagocytosis. The process of phagocytosis is markedly influenced by environmental factors and the nature of the bacterium and leucocytes used, as well as by the amount of opsonin present. Departures from a neutral or very slightly acid reaction or from isotonicity, and the presence of certain ions, notably the citrate radicle, depress the degree of phagocytosis. The last is of practical significance in that it contraindicates the use of citrated blood. The presence of calcium, on the other hand, may restore phagocytic power to leucocytes which have been allowed to stand in isotonic salt solution for a number of hours, a point of some interest in connection with the apparent intimate relation between this ion and cell division and the ability of ameboid cells to form new surfaces.

The nature of the bacterium to be ingested is of considerable importance; in general, virulent forms are relatively resistant to phagocytosis. It is not unlikely that this resistance is associated with the presence of a capsule, in the case of the pneumococcus, for example, not only are the smooth, encapsulated forms highly resistant to phagocytosis, but the presence of capsular polysaccharide markedly inhibits phagocytosis by an immune serum, presumably through combination with the antibody. Bacteriophage (p. 916) renders bacteria considerably more sensitive to phagocytosis.

The phagocytic power or activity of the leucocytes is subject to considerable variation independent of variation in the opsonic content of the blood. This inherent phagocytic power of the leucocytes varies, with respect to certain bacteria at least, even in persons apparently in perfect health. In the child at birth the leucocytes are somewhat less active phagocytically than in the adult; they grow less active for a few months, and then more active, the adult standard for streptococci, pneumococci and staphylococci being reached about the third year. In pneumonia, scarlet fever and other conditions in which there is acute leucocytosis when the outlook is favorable, the phagocytic power of leucocytes has been found to be greater than normal for the specific bacteria. The increase in activity in such cases may be due to the predominance of young leucocytes.

The Process of Phagocytosis. The mechanism of ingestion is essentially one of the interplay of interfacial forces. A formulation of the free surface energy relationships at the points of contact between particle and cell and their respective liquid interfaces has been worked out by Fenn⁴² and subjected to experimental tests by Mudd⁴³ and his associates. Low interfacial tension of the bacteria against the leucocytes—and high interfacial tension against the medium—favors ingestion. The immune opsonins, and to some extent the

⁴² Fenn: *The Newer Knowledge of Bacteriology and Immunology*. Jordan and Falk, University of Chicago Press, Chicago, 1928. p. 861.

⁴³ The process of phagocytosis is discussed at length by Mudd, McCutcheon and Lucke. *Physiol. Rev.*, 1934, 14 210.

Similarly (Greenwood *et al.* 1936), the results obtained in experiments with the virus disease, ectromelia, indicated that some 80 per cent. of the mice entering the herd were infected with the virus within three weeks of entry (see also Fenner 1949b).

The way in which the bacterial parasites are distributed among the hosts at the time of infection is of course of great importance in determining the results in immunization as well as, or in place of, the production of overt disease? That survivors from an epidemic are, on the average, more resistant than new-comers to an infected herd is certain; for they live longer—usually much longer—when exposed to a subsequent wave of mortality (Topley 1921, Amoss 1922).

This increase in resistance with increasing herd experience under epidemic conditions can be studied in greater detail by constructing life tables for the mice submitted to risk of infection during a long-continued prevalence of such a disease as mouse typhoid. It is convenient in calculating the expectation of life to limit it to 60 days, regarding any mouse living for longer periods as dying on the 60th day, since the use of the unlimited expectation of life gives undue weight to the relatively few mice that live for much longer periods, and also because we have a normal standard of comparison for the shorter period, but none for the latter.

Employing this value ($_{60}E_x$) we find in a particular experiment, in which 3 normal mice were added to an infected herd each day from March 6th, 1921, to June 30th, 1923, that the limited expectation of life drops slightly (from 22.49 to 21 days) during the first week of herd life and then rises, at first slowly, but more steeply after the 15th day, until by the 33rd day it reaches the figure of 34.75 days. It fluctuates round this figure up to the 100th day of herd residence; after which the numbers of survivors are too small to give a reliable average. In general then, we may say that a mouse that has survived about 30 days' exposure to risk will live more than half as long again as a new-comer to the cage (Greenwood and Topley 1925, Greenwood *et al.* 1936).

We can ask the same question in another way, using a direct experimental comparison instead of a life table. In a particular experiment (Greenwood, Newbold, Topley and Wilson 1926) in which mouse pasteurellosis was the infection selected for study, two parallel epidemics (A and B) were initiated on November 11th, 1924, and were maintained by the addition of normal mice until December 1925. At regular intervals groups of mice that had survived for 10, 20, 30, 40, 50 days or more in Herd A were transferred to Herd B, and with them were added a numerically equal group of normal mice that had had no previous experience of pasteurellosis. Averaging the results, the figures shown in Table 85 were obtained:

TABLE 85

Length of Life in Herd A.	Expectation of Life in Herd B ($_{60}E_x$).
Nil (normal entrants to B)	22.37 \pm 0.36 days
10 days	21.34 \pm 1.10 "
20 "	25.50 \pm 1.13 "
30 "	32.55 \pm 1.28 "
40-45 days	33.08 \pm 1.52 "
50-60 "	37.39 \pm 1.69 "

Here, again, survival through a testing period of 30 days or more added some 50 per cent to a mouse's expectation of life under severe epidemic conditions.

But clearly we cannot, in the absence of further evidence, assume from such

"normal" opsonins, apparently form a surface deposit on the bacterial cells which promotes phagocytosis by altering the interfacial tension in this manner. In addition to surface tension, other factors such as the viscosity of the phagocytic cell substance enter into this phenomenon. Physical tensions are not the sole controlling factors, however, for increased oxygen consumption accompanies the process of ingestion, the rise beginning at once, reaching a maximum value twice that at the start in about fifteen minutes and persisting for 90 to 150 minutes.

It is of some interest that bacterial cells may be artificially "opsonized," i.e., made more readily phagocytatable, by treatment with iron ammonium alum, chrome alum, protamine sulfate or gallotannic acid. The effect is reversed by treatment with oxalate but reversion is very difficult when the cells are sensitized with immune opsonin. The significance of such observations in immune opsonization and phagocytosis is not clear.

The work of Wood and his co-workers⁴⁴ has shown that phagocytosis may occur quite as readily in the absence of antibody as in its presence, provided that it occurs on a suitable surface; most body tissues provide such surfaces, viz., the phagocytosis of pneumococci on the alveolar surfaces of the lungs. This phenomenon of "surface phagocytosis" has not been previously described.

The Fate of Ingested Bacteria. Following phagocytosis many, but not all, species of bacteria may be observed to undergo a process of dissolution, with swelling, granulation and fragmentation appearing as successive stages in their destruction. Although it was early supposed that intracellular digestion was no more than intracellular lysis through the agency of the immune lysin and complement which would have occurred whether or not phagocytosis took place, it now seems probable that the two processes are essentially different.

Bacteria are no exception to the rule that living organisms are not subject to attack by digestive enzymes, and the question arises as to whether death is a necessary preliminary to ingestion or whether it may occur within the phagocyte. It is probable that the viability of the microorganism is not an important factor in phagocytosis; in most cases the cell may be engulfed whether it is living or dead. In the case of those bacteria which are destroyed within the leucocyte, killing is necessary before digestion can take place. Killing of a viable bactericidal substance not equally viable within bacteria are

protected against the action of immune serum, i.e., bactericidal or lytic antibodies, and this is possibly of some significance in the dissemination of bacteria within the host in the event that they remain viable and are later freed from the leucocyte. Leucocytes have been shown to contain a variety of digestive enzymes, including proteases, lipases and various carbohydrate-splitting ferments which are presumably responsible for the actual dissolution of the bacterial cell.

The Nature of the Opsonic Activity. The opsonins are true antibodies in that they are increased by immunization and exhibit the specificity characteristic of the immune antibodies. The activity is, like that of the lytic sera, made

⁴⁴ Wood, Smith and Watson: Science, 1946, 103 28.

that entered herd B on the same days as these particular groups of migrants from herd A was 20.9 ± 0.49 days; for those migrants that had spent 50 days in herd A it was 34.6 ± 4.10 days.

It may be noted also that such evidence as is available (Topley, Wilson and Lewis 1925, Greenwood and Topley 1925) indicates that the increased resistance gained by survival in an infected herd, or after experimental infection by feeding or inoculation, is specific in the ordinary bacteriological sense. A mouse that has survived infection with *Salm. typhi-murium* appears to be no more resistant than normal mice to infection with *Pasteurella muriseptica*. This, of course, accords well with epidemiological experience in general, but not with the view that the determining factor in increasing the average resistance of a herd at risk is the selection by the sieve of death of those individuals possessing an innate non-specific resistance. If differences in innate resistance are of major importance it would appear that they must either be specific or must be differences of immunizability rather than of immunity.

Whether or not active immunization is the main factor that determines the increased average resistance of surviving mice, the grade of antibacterial immunity produced can excite little enthusiasm.

As stated above, the expectation of life limited to 60 days was selected in these and subsequent experiments, in part because there is an available standard of reference for this period (Greenwood, Topley and Wilson 1931b). On October 4th, 1929, 20 normal mice were assembled in a cage of the same type as that used in all epidemic experiments. From then onwards until January 17th, 1930, daily additions of normal mice were made, and the herd was then observed until May 27th, 1930. The 329 mice of this experiment were living under exactly the same conditions as the infected herd, except that no infection was present at any time during the period of observation. Of these 329 mice 56 died. The limited expectation of life, as was to be expected, remained practically constant at all cage ages from day 0 to day 170—the last day for which figures were available. The lowest $_{50}E_x$ figure was 56.69 days, the highest 59.27 days. The figure rose slowly from just under 57 days on the day of entry to over 58 days on the 40th day of cage life—presumably as the animosities of first acquaintance were replaced by the toleration of later herd life and fighting grew less frequent. Thereafter it hardly varied.

Taking a figure of 58 as our normal $_{50}E_x$, we note that the best that natural immunization against mouse typhoid or mouse pasteurellosis can do—so long as surviving mice are exposed to a continuous risk of heavy infection—is to raise the expectation of life from a little under a half to a little over two-thirds of the normal figure. This is a very different picture from that presented by our study of diphtheria in man—even allowing for the fact that in the latter case we are dealing with a disease of relatively low fatality. Either mice differ in some fundamental way from men; or the conditions in mouse cages differ fundamentally from those in schools and institutions—an obvious possibility; or natural immunization against enteric infection or against pasteurellosis is less effective than natural immunization against diphtheria or scarlet fever. Perhaps, though by no means certainly, this might be expanded to the conclusion that natural antitoxic immunization is much more effective than natural antibacterial immunization.

There is no known disease of mice that presents any close analogy with such toxæmic human infections as diphtheria and scarlet fever; but the description by Marchal (1930) of a natural virus disease of mice—ectromelia—that gives rise to severe and fatal epidemics under experimental conditions has afforded an opportunity for the study of natural immunization against a virus infection. The results

up of two components, one thermostable and the other thermolabile. The thermolabile component is present in normal serum and the reduced opsonic powers of an inactivated immune serum may be restored by the addition of a small amount of normal serum. In this and other respects the thermolabile component of opsonin strikingly resembles complement and in the past has been assumed by many to be identical with this component of the lytic system. In general, however, it has not been possible to show any constant relation between the components of complement and opsonization. For example, the fourth component of complement has been reported⁴⁵ to be necessary to the lytic reaction but not required for opsonization, but Ecker⁴⁶ has reported that the thermolabile opsonin of the human serum is identical with C'_1 , C'_2 and C'_4 in combination but not separately or in any combination of two. It ap-

Fig 35. The phagocytosis of typhoid bacilli by leucocytes in whole blood. Note the enormous numbers ingested by the white cells and the bacilli lying free. Hastings' stain; $\times 1200$.

pears, then, that complement and the thermolabile element of opsonin, while resembling each other closely in many respects, may not be regarded as identical.⁴⁷

There is some question as to whether the thermolabile factor is essential to phagocytosis, for experimental evidence has been presented⁴⁸ which indicates that while the thermolabile factor contained in normal serum markedly accelerates the rate of phagocytosis, approximately the same number of bacteria are ingested at the end of eight hours by phagocytes in the presence of heated serum alone.

Agglutinins. If the blood or serum of an animal previously immunized against a bacterium be mixed with a suspension of the microorganisms, the latter become immobilized and in a short time aggregate to form large clumps of cells. In the test tube these clumps settle out, and the turbid bacterial sus-

mice showed a partial but ineffective immunity in that they lived on the average far longer than the controls but succumbed to the disease during the period of observation; 24 per cent. showed a more effective resistance by living in apparent health throughout the period of observation, but post-mortem examination showed that they were suffering from a latent infection; 18 per cent. appeared to have been rendered completely immune to this dose of bacteria, in that they remained in apparent health for 28 days and showed no evidence of infection when killed and examined by spleen culture. These results may be taken as representative of a considerable number of similar experiments.

TABLE 87

Normal	50	50	5.0 days	—
Vaccinated . . .	50	29	18.3 "	12

We should not perhaps expect an immunity of this order to be very effective as a prophylactic measure in herds submitted to a continuous risk of infection, and actual trial confirms our lack of faith.

An epidemic of mouse typhoid was started on January 1st, 1928, and was continued until September 17th, 1929, by the addition of 3 normal mice a day (Greenwood, Topley and Wilson 1931a). Every 7th day 10 additional normal mice, and several groups, each of 10 mice, that had been immunized with different vaccines were added to the cage. The results, as they concern the relative efficacy of different antigenic components, have already been noted on p. 1201. We are concerned here only with the results obtained with the most effective vaccines employed.

The limited expectation of life ($_{60}E_x$) of the normal mice on entry was 26.26 ± 0.641 days; for the four immunized groups that had received vaccines containing the smooth surface antigen the $_{60}E_x$ figures were 32.10 ± 0.432 , 34.97 ± 0.845 , 35.06 ± 0.845 and 33.71 ± 0.853 days respectively. Thus by active immunization with a killed vaccine an increase in average resistance was obtained of the same order as that attained naturally by normal mice after living for some 30-50 days in an infected herd under the joint influence of active immunization and mortality selection.

After 60 days' residence in the cage the $_{60}E_x$ figures for the vaccinated and unvaccinated groups have, as we should expect, largely levelled up, though the vaccinated mice still show a slight advantage. The figure for the unvaccinated group has risen to 36.47 days, those for the vaccinated groups to 40.17, 37.39, 36.90 and 47.54 days respectively.

Very similar results were obtained in another experiment in which a comparison was made between the effect of administering a killed *Salm. typhi-murium* vaccine by the mouth, or by intraperitoneal inoculation (Greenwood, Topley and Wilson 1931c). A larger dose was used for *per os* than for intraperitoneal immunization ($5,000 \times 10^6$ as against $1,000 \times 10^6$) with a week's interval after the second dose of

vaccine. The experiment lasted from December 14th, 1929, to June 26th, 1930. The death rate in this epidemic was rather lower than in those referred to above, and the expectation of life of the normal mice on entry was therefore somewhat longer. The $_{60}E_x$ figures on the day of entry were as follows: normal mice 31.18 ± 1.04 days, mice vaccinated *per os* 35.30 ± 1.22 days, mice vaccinated intraperitoneally 38.19 ± 1.17 days.

The immunity to ectromelia induced by vaccinating mice with a formalized

pension is cleared with the formation of a precipitate-like mass of clumped cells in the bottom of the tube. This phenomenon is termed *agglutination* and the bacterial cells are said to be *agglutinated*. The bacteria are not killed by agglutination and will, in fact, grow in immune serum although with altered morphology and the formation of long chains of bacillary forms—the so-called “thread reaction” of Pfaundler. Living bacteria need not be used for the agglutination reaction, for dead bacteria are agglutinated as readily as the viable forms.

Although many species of bacteria may be clumped by “normal” sera in low (1:5 to 1:10) dilutions, the capacity of a serum to agglutinate bacteria is greatly enhanced by immunization; high-titered antisera may be prepared which will bring about agglutination in dilutions of 1:20,000 to 1:50,000. The agglutination reaction is, then, an antigen-antibody reaction and the antibody is designated an *agglutinin*. The antigen is sometimes termed an *agglutigen*. The agglutinin does not require the cooperation of complement or other heat-labile substances and inactivated sera will agglutinate to titer.

Not only bacteria but a variety of free cells, including erythrocytes and others, are agglutinated by normal and immune sera. The incompatibility of human blood groups is a consequence of the presence of hemagglutinins. Hemagglutinins are also formed by some bacteria and may possibly be instrumental in the formation of the thrombi observed in the blood vessels after death from certain of the infectious diseases.

the cooperation of a heat-labile component. The reaction may be observed microscopically by mixing a suspension of bacteria and diluted antiserum on a slide but is most commonly carried out by mixing the two in 0.5 to 1.0 ml. amounts in small test tubes and observing the formation of a precipitate. In the latter instance, varying dilutions of serum (frequently prepared in geometrical progression by mixing with an equal amount of physiological salt solution, i.e., 1:10, 1:20, 1:40, 1:80, etc.) are added to the bacterial suspension and incubated at 37° overnight or at 55° C. for two hours. The highest dilution showing observable flocculation is taken as the titer of the serum; a serum showing agglutination in a dilution of 1:10,000 but not in 1:20,000 is said to have an agglutinin titer of 1:10,000. Such titers are variable to some degree depending upon the density of the bacterial suspension and other factors, light suspensions, for example, showing only a faint turbidity to the eye will give higher agglutinin titers than heavy suspensions.

Cross Reactions. Although the agglutination reaction is highly specific, certain cross reactions between closely related bacterial species are frequently observed. Such reactions are attributable not to a lack of immunological specificity but to the immunological heterogeneity of the bacterial cell. As indicated above, the cell is made up of a variety of antigenic components, an “antigenic mosaic.” Clearly, then, if the same component is present in each of two species of bacteria, an antiserum prepared against the one will agglutinate the other but generally to a reduced titer, i.e., only in the lower serum dilutions. This sharing of antigenic components and the resulting cross reactions

kind to that of intraperitoneal immunization, though the resistance induced is slightly inferior.

In the case of the virus disease, ectromelia, the natural immunizing response is far more effective. The immunity attained is not complete—old survivors sometimes die of typical ectromelia, even though they have passed through a charac-

teristic attack many months earlier—but it is of a high order. In conformity with this, vaccination with a formolized virus greatly increases the expectation of life of the mice exposed to risk.

It is clearly of interest to determine the effect of immunizing all entrants to an infected herd. Will this procedure result in the elimination of the disease, at least in its overt form? In the particular case of mouse typhoid, it will not.

In an experiment designed to test this point (Greenwood, Topley and Wilson 1931c) 3 normal mice were added daily to an infected herd from March 15th, 1929, to May 12th, 1929. The limited expectation of life on entry of these mice was 27.00 ± 1.019 days. From May 13th, 1929, to October 20th, 1929, 3 immunized mice were added daily instead of the 3 normal mice, and from October 21st, 1929, to June 29th, 1930, 1 immunized mouse

the three-a-day period was 34.92 ± 0.684 days, for those added during the period it was 36.38 ± 0.938 days—results very similar to those recorded above. But mouse typhoid was spreading and killing as actively in June 1930 as it was in March 1929. The mice at risk lived a little longer, but that was all.

It would, of course, be quite wrong to conclude—even if we may justifiably argue from mice to men—that active immunization of such a kind is useless. As has been noted above, it is capable of completely protecting a proportion of mice

are particularly common among the paratyphoid *Salmonella* and dysentery bacilli. The agglutinins responsible for such cross reactions are sometimes referred to as "group agglutinins" and the phenomenon as "group agglutination."

Agglutinin Absorption. The direct demonstration of the antigenic heterogeneity of a bacterium and the consequent multiple antibody content of its homologous antiserum are made possible by agglutinin absorption. If a heavy suspension of bacteria is prepared in diluted (commonly 1:50) antiserum, incubated for two to three hours, and centrifuged, the supernatant diluted serum will be found to have lost its ability to agglutinate the bacterium with which it was absorbed; the agglutinins for that microorganism have been taken up by the bacterial cells, leaving other agglutinins intact. In practice it is necessary to absorb two or three times and, since the phenomenon is an adsorption, it is not always possible to remove completely the agglutinins in question.

Fig. 36. The macroscopic agglutination test—*Salmonella*. The control tube, C, contains bacterial suspension in the numbered tubes are 1 100, 1:200, 1 500, 1:10,000, 1:20,000. Note agglutination in 1 10,000 but not in 1:20,000.

This preferential absorption makes possible the breakdown of the antigenic mosaic of the bacterial cell into component parts. For example, an antiserum prepared against a bacterium containing antigens A, B and C will contain antibodies *a*, *b* and *c*. If such an antiserum is absorbed by a second bacterium which contains antigens B and C, antibodies *b* and *c* will be removed leaving *a* intact, and the antiserum will still agglutinate its homologous bacterium. Suppose an antiserum is prepared against the second bacterium which will contain antibodies *b* and *c*. If this serum is absorbed by the bacterium containing antigens A, B and C, it will no longer agglutinate its homologous antigen, for all the antibodies will have been removed. Clearly, then, the complete absorption of a known serum by an unknown organism does not indicate that the unknown organism is necessarily immunologically identical with that with which the known serum was prepared; to prove such immunological identity a "mirror absorption" must be carried out, *i.e.*, each antiserum absorbed with each organism.

The agglutination test and agglutinin absorption, although used to some extent in the diagnosis of infectious disease (as in the Widal test in which typhoid bacilli are mixed with patient's serum), have been found particularly valuable in the study of the relation of bacterial species to one another and in

of appeal; but neither from this source nor from any other should we accept hasty judgments.

The experimental data at present available may be summarized as follows:
